Crohn disease can be found along the entire gastrointestinal tract; involvement is often discontinuous ("skip areas"). In 30% of cases, only the terminal ileum is involved; 20% of patients have colonic disease only. Both small and large bowels are affected in the remaining 50%. Disease of the mouth, esophagus, and stomach is found in $<1\%$ of patients. The lesions of Crohn disease tend to involve all of the bowel wall layers and extend into the mesentery. Deep ulcerations, which often penetrate the bowel wall, are common and account for the development of fissures, fistulas, and abscesses; about 25% of patients with Crohn disease will manifest these perianal complications.

CLINICAL PRESENTATION

The most common signs and symptoms in patients with Crohn disease are chronic or nocturnal diarrhea, abdominal pain, fever, anorexia, rectal bleeding, and weight loss. This constellation of symptoms characterizes 75% to 80% of patients with this disorder. Presenting complaints in the ED vary, depending on the site of involvement of Crohn disease. Patients with primary ileal disease present with right lower quadrant abdominal pain associated with fever, abdominal distention, vomiting, and either profuse watery diarrhea or decreased output of stool and gas. Severe cases of

fulminant colitis in Crohn disease are characterized by abdominal pain associated with fever and massive diarrhea. Less common presentations include severe epigastric pain similar to peptic ulcer disease, acute pancreatitis, and large aphthous oral ulcers.

As in Crohn disease, the presentation of UC is quite variable and often depends on the anatomic distribution of disease. In fact, separation of the disorders on the basis of clinical findings alone can be very difficult. In mild cases, occasional constipation and rectal bleeding may be the only complaints. In more severe UC, patients have more than six to eight bloody diarrheal stools per day as well as crampy abdominal pain, tenesmus, fever, tachycardia, and anemia. UC is more commonly associated with rectal bleeding, whereas abdominal pain, abdominal masses, and perianal lesions are more common in patients with Crohn disease.

There is often a delay of several months from the onset of symptoms to the time the diagnosis is established. Therefore, failure to suspect IBD and refer patients appropriately is not uncommon; a high index of suspicion must be maintained in the ED for any patient with recurrent abdominal complaints. Patients with previous episodes of similar gastrointestinal symptoms, family history of IBD, perirectal disease, or any extraintestinal manifestations (rashes, back pain, arthritis, or iritis) that might suggest the diagnosis should be referred to an appropriate specialist for diagnostic workup.

A common reason for patients with well-established IBD to present to the ED is complications of their underlying disease. The major intestinal complications of Crohn disease and UC include intra-abdominal abscess formation, bowel perforation, massive hemorrhage, intestinal obstruction, dehydration, perianal complications (fissures, fistulas, and perirectal abscesses), and fulminant colitis with or without toxic megacolon (5). Massive hemorrhage, fulminant colitis, and toxic megacolon are more commonly seen in UC, whereas abscesses, obstruction, and perianal complications are more typical of Crohn disease. In addition to recognizing these complications, the emergency physician must also be aware that medications taken by patients with IBD, particularly corticosteroids and immunosuppressive agents, may mask the

findings typically associated with complications of IBD. Other drug-associated complications include leukopenia, thrombocytopenia, fever, infection, diarrhea, and pancreatitis, as well as renal and hepatic insufficiency (Table 111.1).

TABLE 111.1
Medication Side Effects in IBD

Medication	Side Effects
Corticosteroids	Acne, hirsutism, fluid retention, fat redistribution, hypertension, hyperglycemia, psychoneurologic disturbances, cataracts, growth failure in children, osteonecrosis
Mesalazine	Nausea, dyspepsia, rare nephritis, pulmonary infiltrates, rare idiosyncratic worsening of IBD
Sulfapyridine	Headache, nausea, vomiting, anorexia, epigastric pain, rare hypersensibility hepatitis, hemolytic anemia, pancreatitis, reversible sperm abnormalities, worsening of IBD
Azathioprine/mercaptopurine	Pancreatitis, bone marrow suppression, nausea, vomiting, hepatotoxicity
Methotrexate	Nausea, leucopenia, hepatic fibrosis, eosinophilic pneumonia
Cyclosporin	Nephrotoxicity, hypertension, headache, gingival hyperplasia, paresthesias
Tacrolimus	Headache, insomnia, nephrotoxicity
Infliximab	Infusion reactions, delayed hypersensitivity-like reactions, drug-induced lupus, tuberculosis reactivation, severe infections, cancer, non-Hodgkin lymphoma, demyelinating process
Metronidazole	Nausea, metallic taste, coating of tongue, peripheral neuropathy
Ciprofloxacin	Taste disturbance, gastrointestinal effects, tendonopathies

Modified from Danese S, Semeraro S, Papa A, et al. Extraintestinal manifestations in inflammatory bowel disease. *World J Gastroenterol*. 2005;11(46):7227–7236.

Toxic megacolon is perhaps the most significant complication seen in patients with IBD (6). This complication develops in 5% of adults with IBD but is rare in children. Toxic megacolon results from loss of muscular tone in the patient with advanced disease. It should

be suspected in patients with active colitis who report a decrease in stool output, particularly if they are on antidiarrheal agents, narcotics, or cathartics, or have undergone recent colonoscopy or barium enema. Affected patients demonstrate findings of fulminant colitis and appear toxic. The abdomen is distended, tender, and tympanitic. Fever, tachycardia, and signs of volume depletion are present. Other findings include mental status changes, leukocytosis, anemia, and electrolyte disturbances. With toxic megacolon, abdominal radiographs demonstrate a long, continuous dilated segment of bowel (>6 cm in width), loss of haustra, and "thumbprinting" as the result of bowel wall edema. Abdominal computed tomography (CT) findings in toxic megacolon include thinning of the colonic wall, distention of the bowel lumen, intramural gas (pneumatosis coli) and, in extreme cases, evidence of perforation. The mortality associated with this complication can be as high as 50% if perforation occurs, although with early recognition, mortality as low as 1% to 2% has been reported.

Twenty-one percent to 36% of patients with IBD have extraintestinal manifestations of their disease (7). Occasionally, these symptoms actually appear before gastrointestinal disease, particularly in children. Extraintestinal manifestations of IBD primarily affect the eyes, skin, joints, kidneys, liver, pancreas, biliary tract, lungs, and vasculature. The most common of these manifestations are arthritis (polyarthritis and ankylosing spondylitis), dermatologic complications (erythema nodosum and pyoderma gangrenosum), ocular inflammation (uveitis, episcleritis, or scleroconjunctivitis), and hepatobiliary disease (cholelithiasis, fatty liver, pericholangitis, chronic active hepatitis, and primary sclerosing cholangitis). In Crohn disease with small bowel involvement, malabsorption syndromes as well as fluid and electrolyte disturbances can occur. Gallstones are found in up to 33% of patients with Crohn disease. Calcium oxalate nephrolithiasis is also common. Patients with IBD may also develop a hypercoagulable state (8), even during periods of disease remission, resulting in deep venous thrombosis, pulmonary embolus and, occasionally, arterial occlusion. Rare involvement of portal veins,

cerebral and mesenteric vasculature, and retinal veins has been reported. Patients with thromboembolic complications have a mortality rate of approximately 25%. Pneumaturia and recurrent urinary tract infection occasionally occur with Crohn disease as the result of enterovesicular fistulas.

A long-term complication, particularly of patients with UC, is colon carcinoma. Patients with UC have had a reported 10- to 30-fold risk of developing colon cancer when compared with the general population, particularly with disease onset before age 25 years. Patients with Crohn disease have a five- to sixfold increase in risk. The incidence of colon cancer has been declining in recent years due to better surveillance and newer biologic therapies. Symptoms of colon cancer may overlap considerably with those of IBD, making diagnosis difficult.

DIFFERENTIAL DIAGNOSIS

The major challenge for the emergency physician is to differentiate IBD as a cause of diarrhea, vague abdominal pain, malaise, and low-grade fever from other treatable causes of these symptoms. Several other entities present with similar complaints. Acute infectious diarrheal illness due to *Shigella, Salmonella, Campylobacter jejuni,* cytomegalovirus, or *Yersinia* species must be considered. Parasitic disease such as amoebiasis can also masquerade as IBD. Cytomegalovirus can cause bloody diarrhea in the patient receiving immunosuppressive agents. When the symptoms primarily involve the rectum, anal intercourse–associated bowel syndrome should be considered. Methicillin-resistant staphylococcal abscesses are commonly found in the perineum and may mimic perianal disease. Symptoms of chronic diarrhea, low-grade fever, and cachexia also occur with HIV infection.

Antibiotic-induced colitis attributable to the overgrowth of *Clostridium difficile* must also be considered, particularly in patients with toxic megacolon. Ischemic colitis and diverticulitis, generally seen in older patients, and radiation colitis may present similarly to IBD.

When abdominal pain is the major complaint, IBD must be distinguished from other causes of the acute abdomen, including appendicitis, cholecystitis, intestinal obstruction, abdominal aortic aneurysm, and mesenteric ischemia. More chronic conditions such as celiac disease, irritable bowel syndrome, and acute intermittent porphyria should be considered in patients with recurrent symptoms. The emergency physician should consider IBD as a cause of abdominal complaints only after excluding other potentially serious causes of abdominal pain.

ED EVALUATION

The emergency physician's first priority is to identify patients with serious complications of IBD, particularly gastrointestinal hemorrhage, intestinal obstruction, bowel perforation, and toxic megacolon, for which aggressive resuscitation and surgical consultation may be required. These occur more commonly in elderly IBD patients (9). Patients may present to the ED with an acute or subacute exacerbation of IBD without evidence of an emergent complication requiring surgical intervention. A careful history should ascertain the frequency of bowel movements, associated symptoms, severity of abdominal pain, and history of hospitalizations. Crohn disease is suggested by such risk factors as a family history of IBD, nonsteroidal anti-inflammatory drug use, and cigarette smoking (10). Physical examination should assess signs of toxicity, dehydration, and metabolic imbalance and should include a careful abdominal examination. Abdominal fullness, mass or a perianal fissure, fistula, mass, or skin tags may be present in Crohn disease (11). Stool should be tested for the presence of blood.

Laboratory evaluation should include a complete blood cell count, blood chemistry profile, urinalysis, and type and screen if bleeding is significant. When liver involvement is suspected, liver function studies should be ordered. Erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and serum albumin may be followed to determine disease activity. Fecal calprotectin and lactoferrin are more sensitive in detecting intestinal inflammation, but, like ESR

and CRP, are nonspecific (12). Plain abdominal radiographs may detect clinically inapparent intestinal perforation, obstruction, or toxic megacolon. Abdominal CT scans differentiate complications of IBD from an acute exacerbation of the underlying disease. Abdominal CTs identify intra-abdominal abscesses, strictures, mesenteric inflammation, and fistulas. The role of abdominal ultrasound as well as CT and MR enterography in diagnosis of IBD complications is currently expanding (13), especially in light of concerns over radiation exposure (14).

KEY TESTING

- Most laboratory tests are nonspecific for the diagnosis of IBD.
- CT scan can help establish the diagnosis, location, and extent of disease, as well as major complications.

ED MANAGEMENT

Patients with significant hemorrhage, obstruction, or perforation as a result of IBD are managed in the same manner as other patients with these conditions. Aggressive fluid management, nasogastric decompression, blood product administration as necessary, and early surgical consultation are indicated. Antibiotic coverage of gram-negative and anaerobic bacteria is appropriate in cases of sepsis, intra-abdominal or perianal disease, or suspected perforation. In patients chronically maintained on corticosteroids, stress doses of intravenous corticosteroids (hydrocortisone 300 to 400 mg/d) also should be administered to prevent symptoms of adrenal insufficiency.

Less critically ill patients admitted to the hospital usually require intravenous fluids, corticosteroids, and sulfasalazine derivatives. A multidisciplinary approach involving gastroenterology, surgery, dietary services as well as nutritional support is needed to best manage these patients. Patients with fulminant colitis with or without toxic megacolon often are given a 24- to 48-hour trial of intensive medical therapy before surgical intervention is considered. Such medical therapy includes aggressive fluid and electrolyte

replacement, nasogastric decompression and bowel rest, and antibiotic coverage for bowel pathogens (enteric bacilli and anaerobes). Intravenous methylprednisolone (60 mg/d) or hydrocortisone (300 to 400 mg/d) is routinely administered. Cyclosporine 2 mg/kg/d has been advocated for severe cases of fulminant colitis (15). Intravenous metronidazole (10 to 20 mg/kg/d) and ciprofloxacin (1 g/d) may be added for intra-abdominal and perianal complications of Crohn disease (16). Should patients fail medical management, surgical consultation may be necessary, though drainage of intra-abdominal abscesses by interventional radiology has become an often-preferred initial option over open surgical procedures. Similarly, obstructions due to adhesions can usually be managed with nasogastric suction alone; however, fibrostenotic strictures cause obstructions that may transiently improve with bowel rest and steroids but often require further intervention including stricturoplasty or resection to prevent recurrence.

For those patients whose flares do not require hospital admission, medication adjustment and follow-up plans should be discussed with the patient's primary care physician or gastroenterologist. Systemic steroids (e.g., budesonide) are the mainstay of treatment for Crohn disease, with immunomodulators (azathioprine, methotrexate) and biologics (infliximab, natalizumab) used to maintain remission (17,18). UC is managed primarily with oral or topical sulfasalazine derivatives (e.g., mesalamine), with steroids, immunomodulators, and biologics reserved for more severe symptoms or extensive disease (19,20). Antidiarrheal agents such as loperamide (imodium) 4 to 16 mg/d or diphenoxylate (lomotil) 5 to 20 mg/d may be prescribed.

CRITICAL INTERVENTIONS

- Recognize serious complications of IBD, such as hemorrhage, obstruction, perforation, and toxic megacolon.
- Initiate aggressive supportive care (including fluid resuscitation, antibiotics, blood products, and steroids) for patients with

serious complications of IBD.

DISPOSITION

Fortunately, most patients with IBD can be managed as outpatients. Criteria for hospital admission include severe manifestations (more than six bowel movements daily, severe abdominal pain, or grossly bloody stool); systemic toxicity (fever, tachycardia, weight loss, and cachexia); those with dehydration or metabolic disturbances; acute complications (intestinal obstruction, bowel perforation, gastrointestinal hemorrhage, and toxic megacolon); and failure of outpatient therapy. Surgical consultation is indicated for complications of the disease, including intestinal obstruction or hemorrhage, perforation, intra-abdominal or perianal abscess or fistula formation, toxic megacolon, and perianal disease. Consultation with a rheumatologist, dermatologist, or ophthalmologist should be considered where extraintestinal manifestations of the disease predominate.

Common Pitfalls

- Mistaking one of the serious complications of IBD (such as abscess, perforation, obstruction, and toxic megacolon) with an exacerbation of chronic symptoms.
- Failure to refer a patient with recurrent abdominal symptoms suggestive of IBD for further diagnostic evaluation.
- Failure to administer intravenous fluids, analgesics, and steroids to patients with an acute exacerbation of IBD.

CHAPTER 112
Diarrhea

Philip N. Salen and Lisa A. Spacek

"Diarrhea" is an alteration in a normal bowel movement characterized by an increase in the water content, volume, or frequency of stools. "Acute diarrhea" is an episode of diarrhea of <7 days in duration; persistent diarrhea lasts more than 7 days (1). Gastroenteritis refers to diarrheal disease associated with nausea, vomiting, and abdominal cramps. In the United States, an estimated 211 to 375 million episodes of diarrheal illness occur annually, resulting in 73 million physician consultations, 1.8 million hospitalizations, and 3,100 deaths (2). In developed nations, morbidity and mortality from diarrhea are rare and occur mainly in the young, the elderly, and the immunocompromised.

Acute diarrheal episodes and exacerbations of persistent diarrhea are common emergency department (ED) presenting complaints. The most common causes of acute diarrhea are infectious; however, there are many less commonly implicated causes, such as chemotherapies and toxins, radiation, food allergies, and inflammatory bowel disease. Among infectious causes of diarrhea, viruses account for 50% to 70%, bacteria for 15% to 20%, and parasites for 10% to 15%. Examples of groups with distinct epidemiologic exposures are: children in day care settings, travelers, individuals engaging in anal intercourse, immunocompromised individuals, people living in unhygienic environments, and those with exposure to contaminated water or foods (1).

Four basic pathophysiologic mechanisms induce diarrhea: alterations in ion secretion from the intestinal villi, alterations in mucosal morphology, alterations in intestinal motility, and osmotic

diarrhea. The majority of diarrheal illnesses are noninflammatory and secretory, usually arising in the proximal small intestine from the action of an enterotoxin or another process that specifically alters the absorptive function of the epithelial cells at the villus tip and results in excessive fluid production (3). Dysentery results from invasive pathogens that elicit inflammation, usually in the colon, and induce fever, abdominal cramps, and bloody diarrhea. In addition to implementing volume resuscitation and treating patients symptomatically, the goal of the emergency physician is to recognize invasive, inflammatory diarrhea, which can signify potential for systemic manifestations of illness, and to determine appropriate therapy.

CLINICAL PRESENTATION

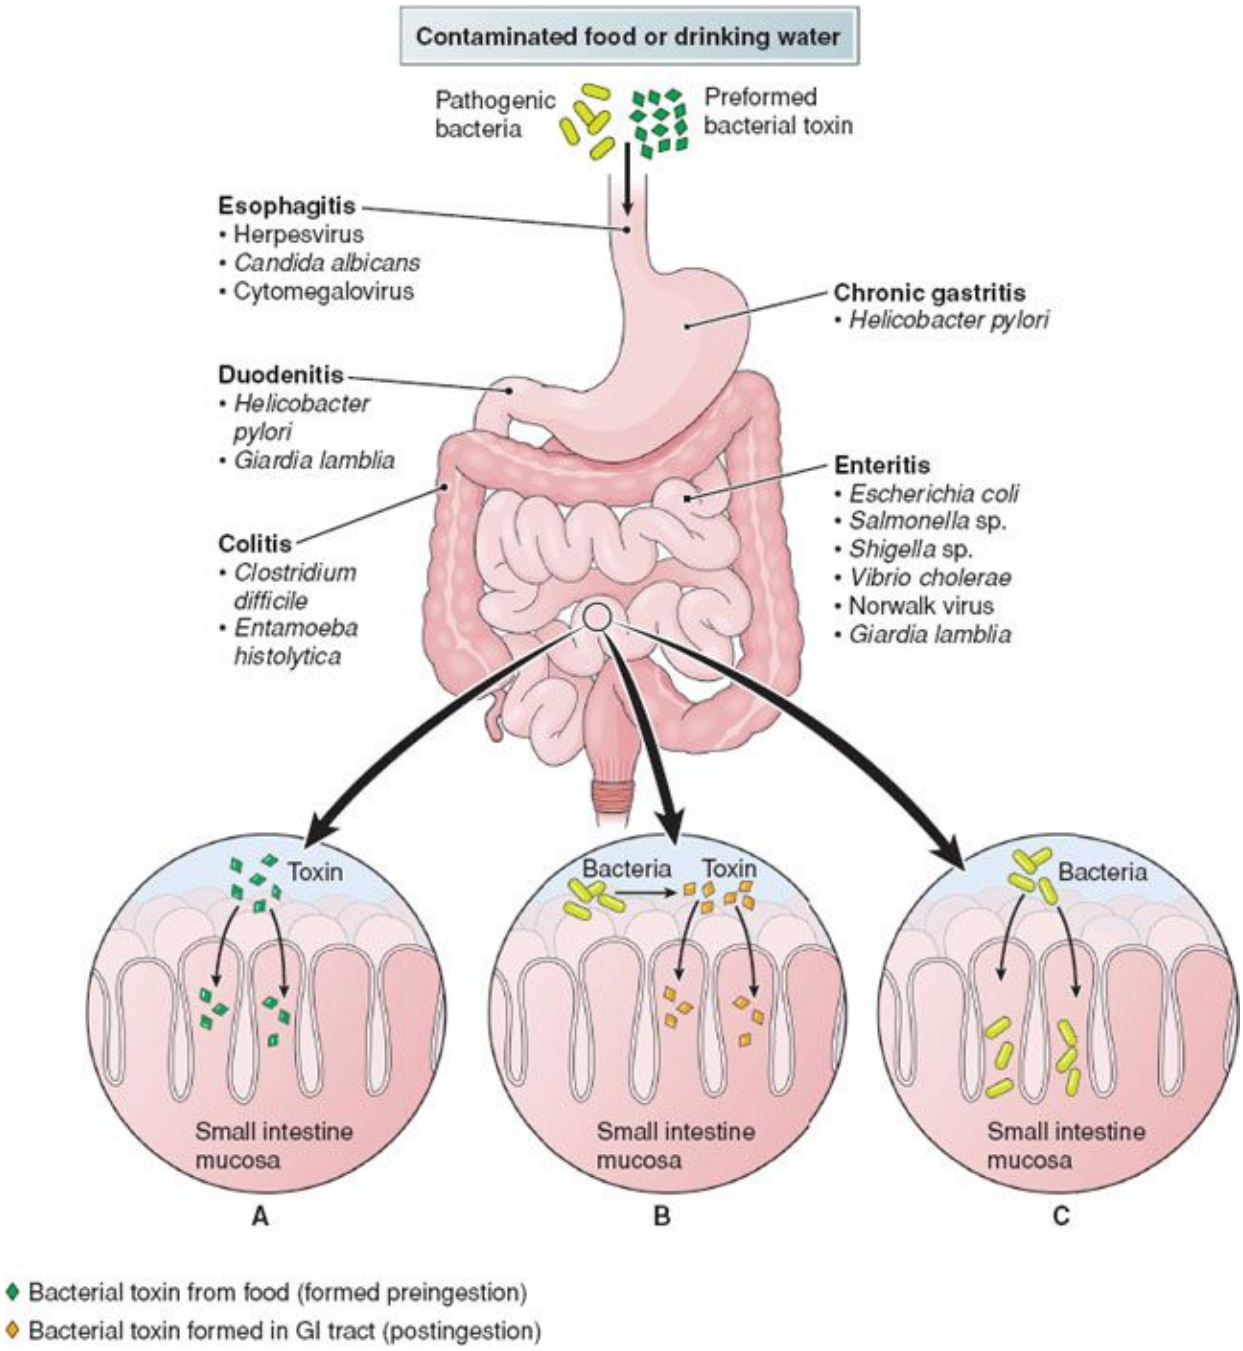
Diarrhea is an increase in stool frequency, an increase in stool volume, or a decrease in stool consistency. Associated gastrointestinal symptoms are nausea, vomiting, abdominal pain, abdominal cramps, bloating, tenesmus, perianal discomfort, intestinal flatus-related complaints, and incontinence. Depending on the etiology, the diarrhea may be: liquid, mucoid, or soft, nonsanguineous or sanguineous, voluminous or scant. Physical examination may reveal fever, tachycardia, dehydration, abdominal tenderness, pronounced borborygmi, and hematochezia. The combination of fever and bloody diarrhea is indicative of intestinal inflammation suggestive of an invasive bacterial colonic disease. From the standpoint of functional impairment caused by the illness, diarrhea may be categorized as mild–moderate, characterized by minimal change in activities of daily living and normal hydration status, or severe, characterized by systemic manifestations of illness and dehydration.

When evaluating complaints of diarrhea, the physician needs to establish whether the stool is truly diarrhea or nondiarrheal rectal discharge, rectal bleeding, or abnormally colored feces. Once the diagnosis of diarrhea is confirmed, the clinician must decide whether (a) there are signs of systemic illness, (b) diagnostic workup is necessary, (c) an etiology can be identified, (d) specific therapy is

warranted, and (e) there are social and community health implications (1). Generally, the severity of illness correlates to the fluid and electrolyte status of the patient and whether the diarrhea has an inflammatory component.

Acute Watery Diarrhea

Many nonbacterial and bacterial enteropathogens are noninflammatory, noninvasive, and act on the proximal small intestine to produce acute watery diarrhea (see eFig. 112.1) (4). Viruses are the most common cause of infectious diarrhea and are characterized by injury to the villus mucosa of the small intestine. Shortened villi decrease the intestinal surface area available for fluid absorption and alter ion secretion. Viral diarrhea is transmitted person to person by the fecal–oral route and by foodborne contamination. The CDC estimates that >50% of US foodborne gastroenteritis outbreaks are caused by the norovirus and rotavirus families (5). Hallmarks of viral enteritis are nausea, vomiting, nonbloody diarrhea, abdominal cramps, malaise, myalgias, chills, and fever in 50% of cases, though the fever is usually low grade. Cholera (eFig. 112.2), an important cause of morbidity and mortality in developing nations that also has low-level endemicity in US Gulf Coast states (4), induces a voluminous, watery, secretory diarrhea via its enterotoxin's effect on the small intestinal villus mucosa that can result in life-threatening dehydration (6). Many potentially important agents that cause watery diarrhea are not detectable by means of conventional stool culture; these pathogens include many types of enterotoxigenic *Escherichia coli,* noncholeraic vibrios, and noroviruses (4).



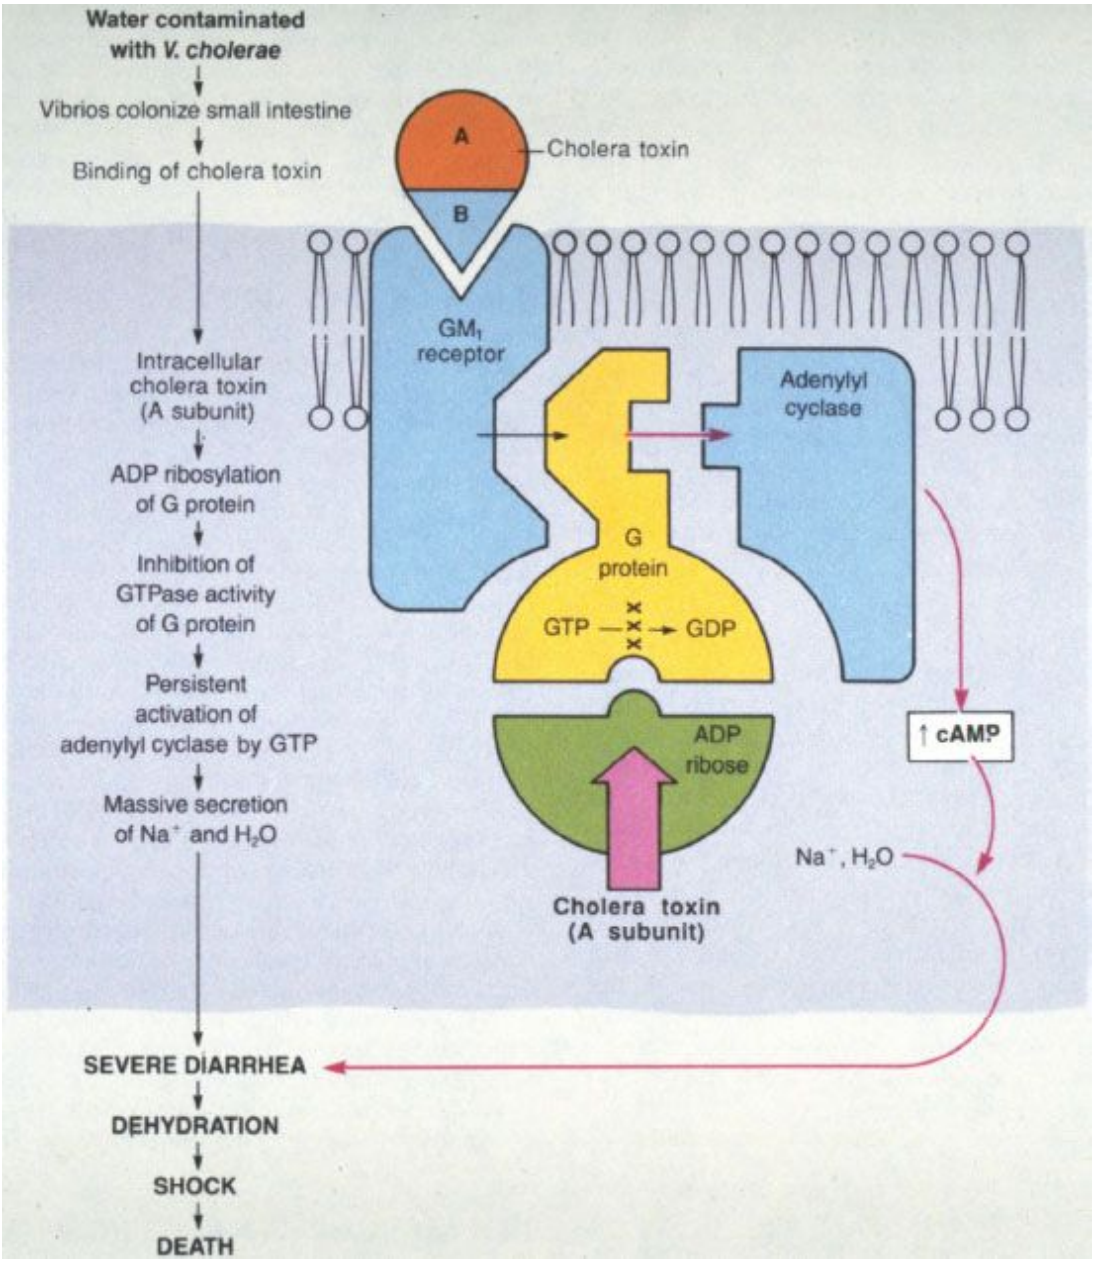
eFIGURE 112.1 Mechanisms of infectious enteritis. Note that pathogens can:

- Produce toxin in food prior to ingestion, which is discussed as food poisoning in this chapter
- Produce toxin in the intestines after ingestion, which can illicit nonbloody diarrhea (cholera is the classic example) or bloody

diarrhea (C. difficile is the classic example)

- Directly invade the bowel wall and cause inflammation (Shigella is the classic example).

McConnell TH. The Nature of Disease Pathology for the Health Professions, Philadelphia, PA: Lippincott Williams & Wilkins; 2007.



eFIGURE 112.2 Cholera. Infection comes from water contaminated with Vibrio cholerae or food prepared with contaminated water. The vibrios traverse the stomach, enter the small intestine, and

propagate. Although they do not invade the intestinal mucosa, the vibrios elaborate a potent toxin that induces a massive outpouring of water and electrolytes. Severe diarrhea ("ricewater stool") leads to dehydration and hypovolemic shock. (Image from Rubin E, Farber JL. Pathology. 3rd Ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

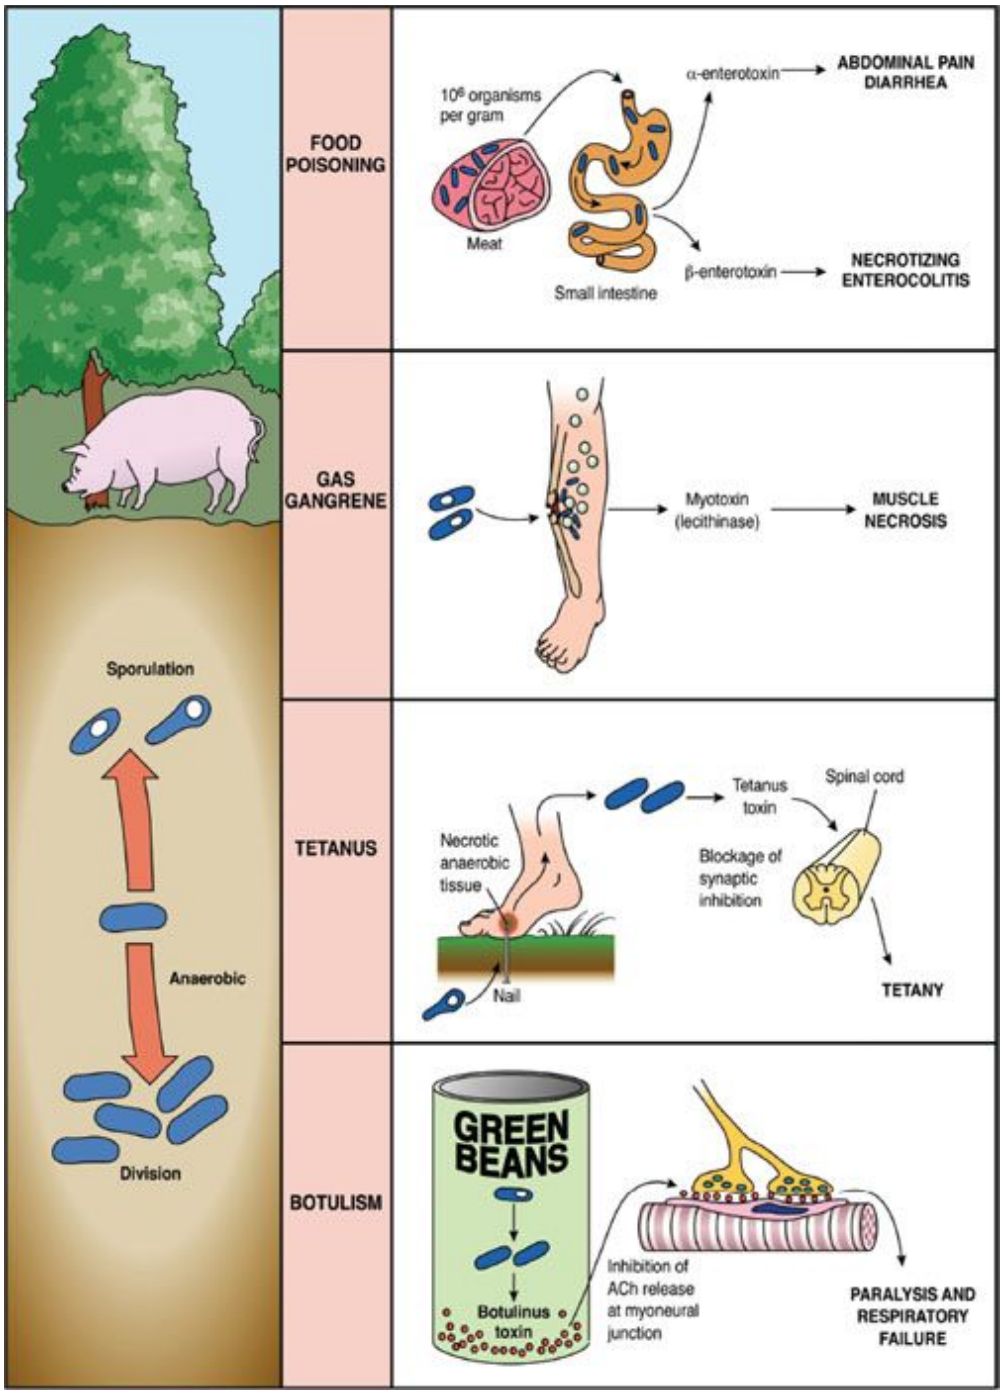
Dysentery

Profuse, explosive bloody diarrhea suggests invasive, bacterial ileocolitis (see eFig. 112.1) (4). Bacterial enteritis alters mucosal morphology by invasion of mucosa of the terminal ileum and colon and induces inflammation. Edema, bleeding, and leukocyte infiltration of the colonic wall manifest as blood and pus in the stool. Fever, which may be quite marked, is a characteristic feature of bacterial enteritis. The four most common causes of bloody diarrhea in the United States, in descending order of occurrence, are Shigella, Campylobacter, nontyphoid Salmonella, and Shiga toxin-producing *E. coli*. Other organisms may also cause dysentery, including *Aeromonas* spp., noncholeraic vibrios, and *Yersinia enterocolitica* (4). It is estimated that only 5% of organisms that cause bloody diarrhea in the United States and that are detectable by laboratory tests are identified (4). Special care must be taken when evaluating patients with suspected dysentery to eliminate the possibility that they may have an anatomic, noninfectious cause of diarrhea and its associated symptoms of abdominal pain and/or fever, such as ulcerative or ischemic colitis.

Food Poisoning

Food poisoning occurs when a preformed toxin in food is ingested resulting in an intoxication rather than an enteric infection (eFig. 112.1) (4). *Staphylococcus aureus* causes vomiting hours after ingestion of improperly cooked food containing a heat-stable preformed toxin. *Clostridium perfringens* causes watery diarrhea without vomiting within 14 hours after ingestion of contaminated meat (eFig. 112.3). Botulism occurs when improperly canned food is

contaminated by the vegetative form of *Clostridium botulinum,* which proliferates under anaerobic conditions and elaborates a neurotoxin. After the food is ingested, the neurotoxin is absorbed from the small intestine and eventually reaches the myoneural junction, where it inhibits the release of acetylcholine (eFig. 112.3). Scombroid food poisoning is caused by consumption of spoiled fish of the Scombroidiae family, for example, tuna, with high histamine levels and manifests as histamine toxicity (7). Symptoms include perioral tingling, headache, flushing, palpitations, truncal rash, abdominal cramps, and diarrhea; treatment with antihistamines is effective. Ciguatera food poisoning, caused by consumption of dinoflagellate toxins in tropical reef-dwelling fish, manifests as abdominal cramping and diarrhea manifest followed by neurologic manifestations, such as reversal of temperature perception (7).

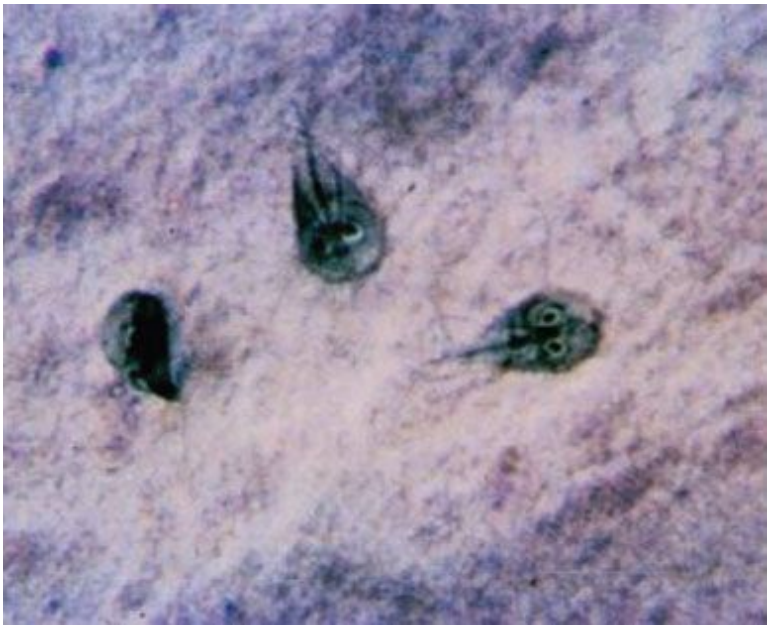


eFIGURE 112.3 Clostridial diarrheal infections meat dishes left to cool at room temperature grow large numbers of clostridia. When contaminated meat is ingested, C. perfringens types A and C produce alpha enterotoxin in the small intestine during sporulation, causing abdominal pain and diarrhea. Type C also produces beta-enterotoxin botulism. Improperly canned food is contaminated by the vegetative form of C. botulinum, which proliferates under aerobic conditions

and elaborates a neurotoxin. After the food is ingested, the neurotoxin is absorbed from the small intestine and eventually reaches the myoneural junction, where it inhibits the release of acetylcholine. (Image from Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

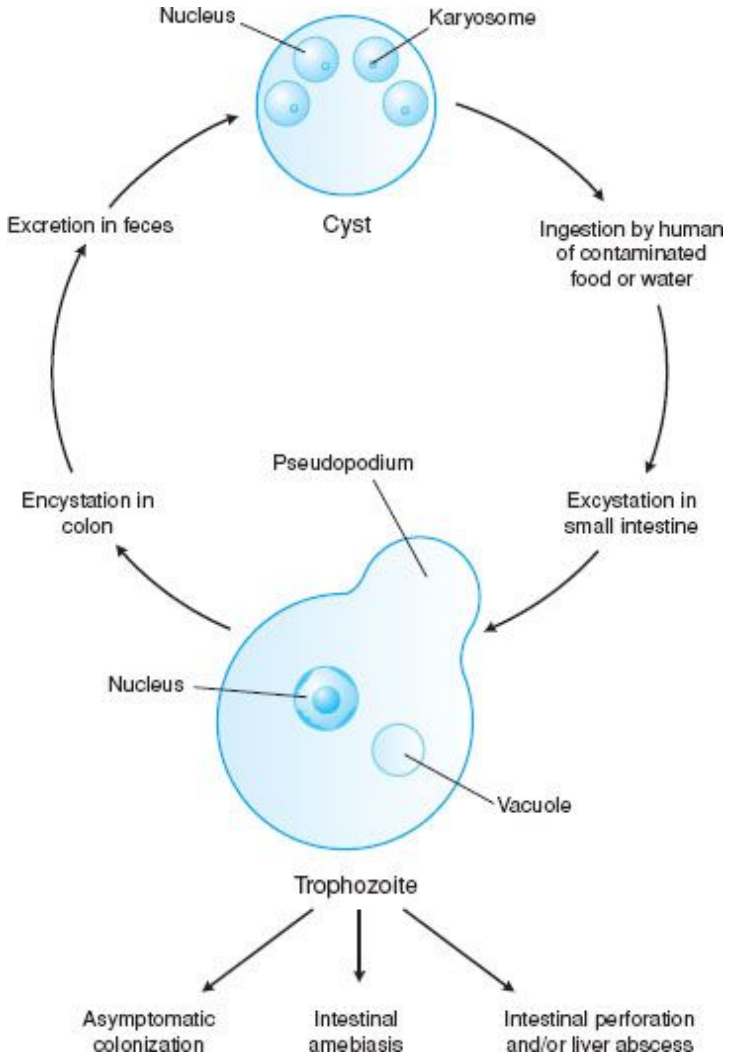
Protozoan Diarrhea

When evaluating patients suffering from persistent, nonspecific complaints of persistent diarrhea such as bloating and excessive flatulence, it is important to consider intestinal protozoa, which are common causes of persistent diarrhea, particularly in the traveler. Protozoan parasites are less common than viral and bacterial causes of traveler's diarrhea (TD), but should be considered in anyone with persistent diarrhea or when antibacterial therapy fails to shorten illness. The most commonly implicated parasites are giardiasis (eFig. 112.4), cryptosporidiosis, and amebiasis (8). *Giardia lamblia* and cryptosporidium-induced diarrhea is noninflammatory, without blood or pus. Giardia and cryptosporidium induce watery diarrhea, abdominal pain, and malabsorption that may last for weeks to months (9). International travel, hypochlorhydria, and ingestion of contaminated water are important risk factors; of note, Giardia is a common pathogen in the United States, particularly amongst campers drinking untreated lake or river water.



eFIGURE 112.4 Microscopic appearance of Giarda lamlia.

Bloody diarrhea in recent immigrants or travelers returning from tropical regions where *Entamoeba histolytica* (see eFig. 112.5) is endemic should prompt stool testing for protozoa (17). Ingestion of cysts of *E. histolytica* from fecally contaminated food or water initiates infection; in addition, infectious transmission is possible via genital–anal sexual contact. Infection with *E. histolytica* cysts ranges from asymptomatic excretion of the cysts to invasive intestinal disease. Invasive disease results when the parasite invades the intestinal epithelium. This invasion induces amebic dysentery, characterized by abdominal cramps and diarrhea, or, in its most severe manifestation, intestinal perforation. Intestinal amebiasis uncommonly causes fecal leukocytes, but commonly induces bloody diarrhea. Hepatic involvement occurs when *E. histolytica* ascends the portal venous system and induces hepatic necrosis from obstruction of portal vessels. Amebic liver abscess is 10 times as common in men as in women and is a rare disease in children. Approximately 80% of patients with amebic liver abscess present with symptoms that develop relatively quickly typically 2 to 4 weeks, which include fever, cough, and a constant, dull, aching abdominal pain in the right upper quadrant or epigastrium.



eFIGURE 112.5 Manifestations of amebiasis. Ingestion of E. histolytica cysts can result in several different clinical outcomes, ranging from asymptomatic excretion of the cysts to invasive disease. Asymptomatic infection occurs when the ingested cysts mature in the small intestine but do not invade the intestinal mucosa. These trophozoites then encyst in the colon, and excretion occurs in the feces. Invasive disease results when active trophozoites invade the intestinal epithelium. This invasion can result in asymptomatic colonization, intestinal amebiasis (amebic dysentery), which is characterized by diarrhea and abdominal cramps, or intestinal perforation. Spread of infection via the portal vein can cause liver abscesses. (Adapted with permission from Huston CD, Haque R, Petri WA. Molecular based diagnosis of Entamoeba histolytica infection. Expert Rev Mol Med. 1999;1999:1–11, Figure 112.1.)

Traveler's Diarrhea

TD frequently occurs in people traveling from developed nations to developing nations and has the potential for wrecking a meticulously planned vacation. TD results because travelers have low levels of immunity against the prevalent pathogens in the food and water in the visited countries (3). The most important and common causes of TD are bacterial with diarrhea-inducing *E. coli,* Shigella*,* Salmonella*,* and Campylobacter inducing the majority of significant illness (10).

Antibiotic-Associated Diarrhea

The spectrum of findings in antibiotic-associated diarrhea ranges from "nuisance diarrhea," frequent loose and watery stools, to life-threatening toxic megacolon. Antibiotic-associated diarrhea may be caused by enteric nosocomial pathogens, by the direct effects of antimicrobial and other chemotherapeutic agents on the intestinal mucosa, and by the metabolic consequences of reduced concentrations of fecal flora (11).

Clostridium difficile infection (CDI) is by far the most common cause of infectious diarrhea in hospitalized patients in North America and the incidence and severity of disease has increased alarmingly since 2000 (12). CDI results in increased morbidity, length of stay, and healthcare costs (11). Most cases of CDI present during or shortly after antimicrobial use. An overgrowth of pathogenic *C. difficile,* which occurs when native bowel flora is killed by antibiotics, produces exotoxins A and B that cause diarrhea (eFig. 112.1). While the majority of CDI results from antimicrobial use, other events may impair colonization resistance, including bowel preparation for colonoscopy or surgery, cytotoxic chemotherapy, and colitis caused by inflammatory bowel disease where colonization by *C. difficile* is common and may exacerbate the underlying inflammatory bowel disease (12). Other risk factors for CDI include age $\leq$65 years, immunosuppresion, and inhibition of gastric acid secretion, especially from proton pump inhibitors (11). Immunocompromised patients contract CDI more frequently and are at increased risk for resultant severe infection and complications. The

most severe manifestations of CDI will result in pseudomembranous colitis and toxic megacolon (eFig. 112.6). CDI relapse is common after therapeutic resolution, occurring in about 25% of cases. Prevention efforts against the nosocomial spread of *C. difficile* includes use of barrier precautions, isolation of infected patients, careful cleaning of fomites with dilute sodium hypochlorite solution, and fastidious hand hygiene. Specifically, hand washing with soap and water is required as a supplement to alcohol-based sanitizers, because such sanitizers do not eradicate *C. difficile* (11).

eFIGURE 112.6 Pseudomembranous plaques seen with colonoscopy in a patient with Clostridium difficile—associated pseudomembranous colitis. (Adapted from Gorbach SL, Bartlett JG, Blacklow NR, etal. Infectious Diseases. Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)

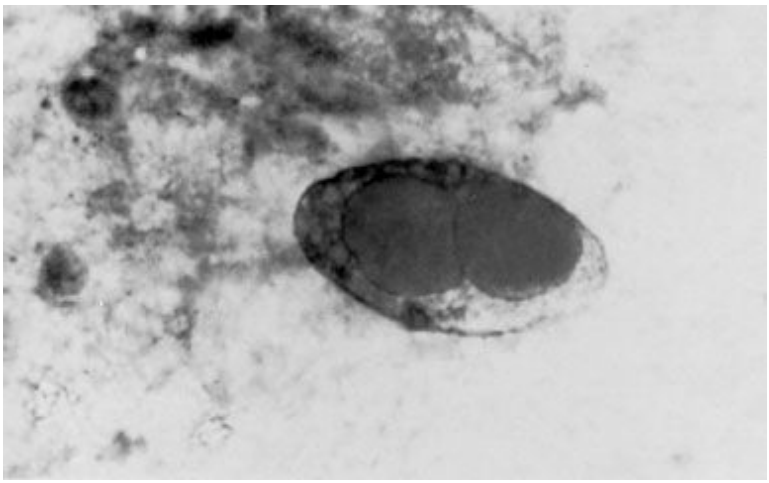
A newly identified hypervirulent strain of *C. difficile,* epidemic strain BI/NAP1 of toxinotype III, has been associated with more frequent and more severe disease, as indicated by higher rates of toxic megacolon, leukemoid reaction, shock, and death (13). This

strain is unique in that it produces substantially more toxin than most hospital strains (14). This emerging strain of *C. difficile* causes disease not only in the hospital setting in traditional at-risk patients but also in patients previously not considered at risk for the disease, specifically immunocompetent, community dwelling, young individuals without recent antibiotic exposure (13).

Diarrhea in Immunocompromised Hosts

Immunocompromised patients present frequently with severe and persistent diarrhea caused by a broad spectrum of infectious and noninfectious etiologies. Besides noninfectious causes, for example, lymphoma, Kaposi sarcoma, or drug-induced diarrhea from highly active antiretroviral therapy (HAART), diarrhea in HIV-infected patients is common and oftentimes caused by opportunistic infections owing to alterations in the mucosal immune system (15). The etiology of their diarrhea is linked to their degree of immunosuppression, which is measured by their CD4+ lymphocyte count. Opportunistic infections most often occur when their CD4+ cell count falls below 100 cells/uL.

Viral, ulcerative infections due to cytomegalovirus and less often herpes simplex virus (HSV) cause chronic inflammatory diarrhea. Cryptosporidium, *Cystoisospora belli* (eFig. 112.7), and microsporidium are opportunistic protozoan pathogens that require specialized diagnostic tests. *Mycobacterium avium intracellulare* infection is associated with fever, bacteremia, and weight loss. Fungal infection with histoplasmosis causes systemic illness that may present as a diffuse colitis. An emerging opportunistic fungus that is endemic in Southeast Asia, *Penicillium marneffei,* causes systemic illness and intestinal ulceration in HIV-infected individuals with CD4 <100 cells/uL, and disseminated disease manifesting with diarrhea and abdominal pain in solid organ transplant recipients (16). HIV-AIDS enteropathy, a pathogen-negative diarrhea that results from CD4+ lymphocyte depletion and failure to maintain the epithelial barrier function of the gut mucosa, is best treated by initiating, or ensuring compliance with HAART to promote recovery of the CD4 count (15).



eFIGURE 112.7 Acid-fast Cystoisospora belli oocyst in the stained smear of a fecal specimen from a patient with AIDS and diarrhea (450×). (Courtesy of Madeleine Boncy, Haitian Study Group on Kaposi's Sarcoma and Opportunistic Infection [GHESKIO], Port-au-Prince, Haiti.)

Diarrhea of Noninfectious Etiology

Consider noninfectious causes of diarrhea when the compendium of diagnostic evaluation has not identified a pathogen (1). Noninfectious and extraintestinal processes may present as acute, persistent, and chronic diarrhea. Some important noninfectious diarrheal diagnoses to contemplate include irritable bowel syndrome, ischemic bowel disease, bowel obstruction, celiac sprue, malabsorption syndromes, and medicinal adverse reactions (e.g., sorbitol, lactulose). Fecal evidence of inflammation in persistent diarrhea should arouse concern about inflammatory bowel disease, particularly if the presence of a treatable inflammatory pathogen, such as Shigella or *C. difficile,* has been ruled out (2).

Potential Complications from Diarrhea

Salmonella and Campylobacter are organisms that deeply penetrate the intestinal mucosa and are prone to cause bacteremia (4). Shiga toxin-producing *E. coli* is a common cause of sanguineous diarrhea that induces colonic vasculitis and allows inflammatory mediators to gain access to the systemic circulation initiating hemolytic-uremic

syndrome. Shiga toxin-producing *E. coli* is differentiated from other bacterial enteric diseases by the absence of fever in the setting of bloody diarrhea (2). Hemolytic uremic syndrome occurs usually within a week after onset of diarrhea and can affect people of any age. Clinical features of hemolytic uremic syndrome include hemolytic anemia, thrombocytopenia, and acute renal failure. Once an isolate has been identified, notify the local health department to identify the source and prevent spread (1). Immune-mediated extraintestinal manifestations such as reactive arthritis and iritis complicate diarrheal illness secondary to Shigella, Salmonella, Yersinia, and Campylobacter. Yersinia infection can induce an autoimmune-type thyroiditis, pericarditis, erythema nodosum, and glomerulonephritis. Guillain-Barré syndrome is an uncommon, late, deadly complication of Campylobacter infection (4).

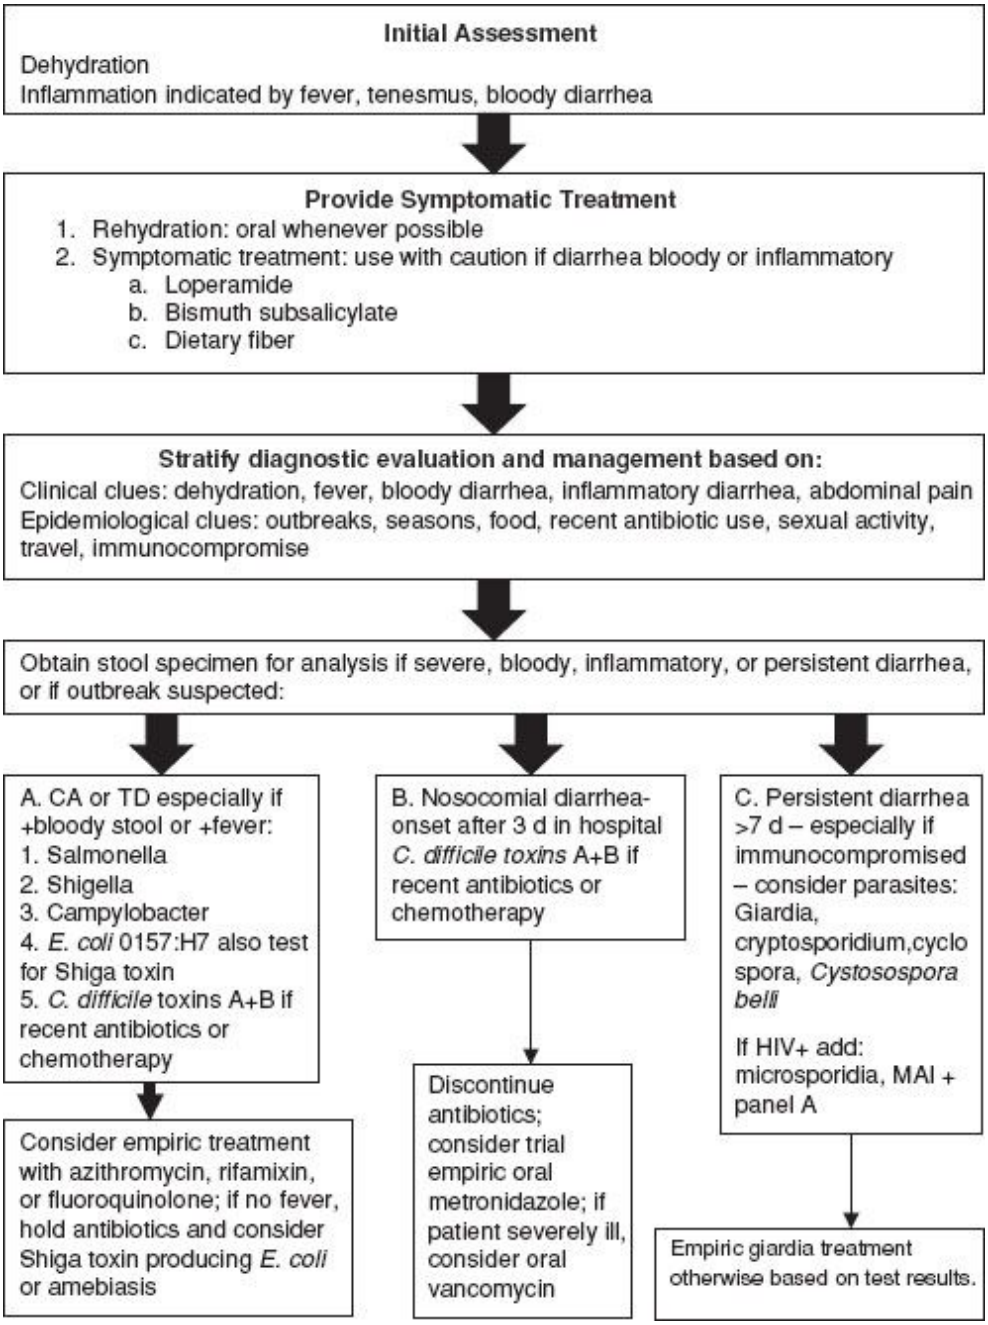
DIFFERENTIAL DIAGNOSIS

Although there are many causes of acute diarrhea, most cases presenting to the emergency physician will be infectious and are transmitted by ingestion of contaminated food or water laden with the organism. Most infectious diarrhea is nonbloody, viral in origin, and will resolve with supportive care. The differential diagnosis of an infectious diarrheal illness with occult or grossly bloody stools includes infection with Shigella, Salmonella, Campylobacter, Shiga toxin-producing *E. coli, E. histolytica* (if recent travel to the tropics), or *C. difficile* (if recent antibiotics or hospitalization) (17). Noninfectious etiologies of bloody diarrhea include inflammatory-bowel disease, ischemic colitis, diverticulitis, radiation colitis, celiac sprue, and malignancy.

ED EVALUATION

Assessment of the severity and duration of enteritis, the presence of dehydration, the character of the diarrhea, and the presence of fever, vomiting, or dysentery aid in identifying diarrheal illness with systemic manifestations. Diarrheal illness can be parsed into four broad categories: (1) community acquired or TD, (2) nosocomial (antibiotic or hospital associated) diarrhea, (3) persistent diarrhea,

and (4) diarrhea in immunocompromised hosts (eFig. 112.8). eTable 112.1 documents epidemiologic, symptomatic, and testing characteristics of important diarrheal pathogens. If there is bloody diarrhea in association with fever, entertain culturing diarrhea for: Salmonella, Shigella, Campylobacter*, E. coli 157:H7,* and *C. difficile.* Consider nosocomial diarrhea in the posthospitalization or postantibiotics patient. For persistent, nonbloody diarrhea, evaluate for parasites and elucidate the patient's immune status. Noninflammatory enteritis typically presents with emesis, mild or absent fever, mild crampy pain, and watery diarrhea, all of which reflect viral disease with small intestine involvement. Inflammatory enteritis presents with fever, significant abdominal pain, tenesmus, and bloody diarrhea, which suggest invasive colonic involvement. Focus physical examination on vital signs, that is, the presence of fever, tachycardia, and hypotension, and the abdomen, which may be tender to palpation and have hyperactive borborygmi, but should lack distension and peritoneal signs.



eFIGURE 112.8 Algorithm for Diarrheal Assessment and Management. CA, community acquired; TD, traveler's diarrhea; MAI, Mycobacterium avium intracellulare.

eTABLE 112.1
Epidemiology, Clinical Characteristics, and Treatment for Selected Pathogens

Infectious Agent	Epidemiology	F	AP	NV	BD	FL	Evaluation	Therapy[a]	Clinical Pearls
Norovirus (e.g., Norwalk virus)	Winter predilection, epidemic outbreaks; most common infectious diarrhea	+/–	+	+	–	–	Clinical	Symptomatic therapy	Hypochlorite 5,000 ppm provides effective surface decontamination (5)
Noncholeraic vibrios	Seafood and shellfish contaminant	+/–	+/–	+/–	+/–	+/–	Specialized stool culture	Doxycycline 100 mg PO BID	*V. vulnificus* most lethal; preexisting liver disease increases risk.
Campylobacter	Contamination of food or water, especially poultry	+	+	+	+	+	Standard stool culture	Azithromycin 500 mg PO QD × 3 d OR Erythromycin stearate 500 mg PO q12h × 5 d	Often resistant to fluoroquinolones; be wary for postinfectious complications
Yersinia	Foodborne contaminant; seen most commonly in northern countries (e.g., Canada, Sweden)	+	+	+/–	+/–	+/–	Specialized stool culture	Ciprofloxacin 500 mg PO bid × 3 d	Can mimic appendicitis symptoms
Shigella	Foodborne and person to person spread	+	+	+	+	+	Standard stool culture	Ciprofloxacin 500 mg PO bid × 3 d	Severe diarrhea; low inoculum required for infection
Salmonella	Primarily foodborne transmission, prevalent in poultry	+	+	+	+	+	Standard stool culture	Ciprofloxacin 500 mg PO bid × 3 d	Reserve antibiotics for systemically ill; antibiotic therapy may prolong fecal excretion
Shiga toxin-producing *E. coli*	Foodborne transmission; also farm animal contact and person to person transmission	–	+	+/–	+	–	Specialized stool culture + EIA for Shiga toxin	Supportive care; hydration	Antibiotic and antimotility therapy ⇑ risk of hemolytic uremic syndrome
Enterotoxigenic *E. coli*	Foodborne transmission	+/–	+	+	–	–	Stool culture for *E. coli*	Ciprofloxacin 500 mg PO bid × 3 d	Common cause of TD
Clostridium botulinum	Preformed toxin ingestion; infants more at risk	–	–	–	–	–	Anaerobic cultures and toxin assays of serum, stool, and implicated food	Supportive	Toxin induces cranial nerve palsies, weakness, and respiratory failure
Clostridium difficile	Nosocomial; postantibiotic complication	+	+	+–	+	+	EIA for toxins A+B	Metronidazole 500 mg PO q6; vancomycin 125 mg PO q6	Increasing virulence; consider adjuvant probiotic therapy
Vibrio cholerae 01 or 0139	Waterborne transmission	–	+/–	+/–	–	–	Specialized stool culture	Azithromycin 1,000 mg PO × 1 dose	Primary therapy is rehydration; without treatment case fatality rate 50%
Giardia lamblia	Contaminated food and water	–	+	+/–	–	–	EIA	Tinidazole 2 g PO once OR Nitazoxanide 500 mg PO bid × 3 d	Most common GI parasite in US
Entamoeba histolytica	Travel to tropics; fecal oral transmission	+	+	+/–	+	–	EIA	Metronidazole 750 mg PO TID × 10 d then paromycin 25 mg/kg/d in 3 doses × 7 d	Consider when TD patient has bloody diarrhea but no fecal leucocytes. Associated with liver abscess
Cryptosporidium	Contaminated water; immunocompromised hosts	+/–	+/–	+/–	–	–	EIA	Nitazoxanide 500 mg PO bid × 3 d	Highly active antiretroviral therapy sufficient to achieve immunologic reconstitution in AIDS patients and resolution of diarrhea
Cyclospora cayetanensis	Foodborne transmission	+/–	+/–	+	–	–	Microscopy	TMP/SMX DS 1 tab PO bid × 7–10 d	Fatigue, which may be profound, is present in ≥90% of patients with cyclosporiasis
Cystoisospora belli	Fecal–oral transmission, contaminated water	+/–	+/–	+/–	–	–	Microscopy	TMP/SMX DS 1 tab PO bid × 10 d	Prevalent in AIDS patients

+, common; –, not common; +/–, occasional; AP, abdominal pain; FL, fecal leukocytes; BD, bloody diarrhea; PO, by mouth; GI, gastrointestinal; EIA, enzyme immunoassay; TMP/SMX, trimethoprim-sulfamethoxazole; DS, double strength.

[a]Therapy. Only adult doses given. Please refer to pediatric diarrhea chapter for specific doses and therapies for children.

Adapted from Guerrant RL, Van Gilder T, Steiner TS, et al. Practice guidelines for the management of infectious diarrhea. *Clin Infect Dis.* 2001;32:331–350; Thielman NM, Guerrant RL. Acute infectious diarrhea. *N Engl J Med.* 2004;350:38–47; DuPont HL. Bacterial diarrhea. *N Engl J Med.* 2009;361:1560–1569.

Documentation of fecal leukocytes, blood, or fecal lactoferrin aids in bedside identification of dysentery. Commonly identified bacterial pathogens in patients with fecal leukocytes include Shigella,

Salmonella, Campylobacter, *E. coli,* Yersinia, *Vibrio parahaemolyticus,* and *C. difficile.* When diarrhea is persistent or recurring, or if the history of fever or hematochezia is equivocal, fecal testing by means of microscopy for polymorphonuclear leukocytes or by means of immunoassay for the neutrophil marker, fecal lactoferrin, can quickly provide additional laboratory evidence to support a presumptive diagnosis of inflammatory diarrhea (2). Fecal leukocytes can also be seen in nonenteritis conditions, such as inflammatory bowel disease.

Relatively well-appearing patients presenting with signs and symptoms of bacterial enteritis can be treated empirically with antibiotics, and stool cultures need not be sent. Stool cultures are not routinely recommended in most cases of watery diarrhea or TD because of the low yield of identification of bacterial pathogens (4). Patients with symptoms of dehydration, severe dysentery, abnormal abdominal examination, or diagnostic uncertainty, warrant further investigation. Systemic illness, fever, or bloody diarrhea should prompt stool testing for Salmonella, Shigella, and Campylobacter; eTable 112.2 lists specific indications for diarrheal cultures. Patients presenting with acute onset of bloody diarrhea, especially if they have no fever, should have stool testing for Shiga toxin along with cultures for *E. coli* 0157:H7 (2). If the patient has been on antibiotics antecedent to diarrheal onset, consider *C. difficile* and test for toxins A and B. Assays for *C. difficile* toxin are not recommended after the completion of a course of therapy as the results may be misleading (2); many patients treated successfully for CDI will continue to shed *C. difficile* and toxins A and B in their stool for some weeks despite complete clinical recovery (12).

eTABLE 112.2
Indications for Stool Culture in Patients with Acute Diarrhea

Immunocompromised hosts
Travel history to developing countries
History of anal intercourse
Failure to respond to empiric antibiotic therapy
Individuals with close contact to others where fecal–oral spread can occur (day-care workers, health care workers, food handlers)
"Toxic" clinical appearance—fever or other abnormal vital signs
Significant abdominal pain
Persistent diarrhea (≥14 days) with suspicion of protozoan cause
Severe, bloody, inflammatory diarrheal illness
Suspicion of antibiotic-resistant bacterial dysentery
Recent antibiotic use
Bloody diarrhea with suspicion of hemolytic uremic syndrome

It is rarely necessary to send stool for ova and parasites during an episode of acute diarrhea. However, illnesses lasting longer than 14 days should prompt consideration of parasites, most notably *G. lamblia,* particularly in travelers who have returned from areas where untreated water is consumed and in immunocompromised patients. Testing of one or two specimens for giardia, cryptosporidium, and amebiasis by means of enzyme immunoassay has a sensitivity of more than 95% and is considerably better than older methods based on microscopical examinations (2). Direct immunofluorescent assays, immunochromatographic assays, and enzyme-linked immunoabsorbent assays are more sensitive and provide speedier results for diagnosis of giardia, cryptosporidia, and amebiasis infections than microscopic ova and parasite examination (9). Stool smear and stain for parasites for direct visualization by microscopy still has a role in the diagnostic evaluation of parasites because, while serology is highly sensitive for extraintestinal disease, it is only moderately sensitive for intestinal disease, and poorly sensitive for asymptomatic infection. In patients with advanced HIV disease, especially those who have fewer than 50 CD4+ lymphocytes per cubic millimeter, consider stool studies for cryptosporidia, microsporidia, cyclospora, and cystoisospora in addition to routine diarrheal cultures. If these stool studies are unrevealing, endoscopy and colonic biopsies for *Mycobacterium avium complex* and cytomegalovirus are indicated (2).

KEY TESTING

- Consider point of care testing for dysentery: fecal occult blood testing, fecal leukocytes, or fecal lactoferrin.
- If suspicion of dysentery, send stool for culture.
- If suspicious for antibiotic associated diarrhea, evaluate diarrhea by enzyme immunoassay for *C. difficile* toxins A and B.

ED MANAGEMENT

The main objectives of ED management of diarrhea are to: (a) provide fluid and electrolyte replacement, (b) prevent spread of the enteropathogens, (c) provide symptomatic relief, and (d) provide specific therapy if warranted.

Fluid and Electrolyte Therapy

Regardless of the causative agent, initial therapy for enteritis must address volume status and rehydration. Unless the patient is comatose or severely dehydrated, oral rehydration with a glucose-based electrolyte solution is preferred (18). The standard oral rehydration solution formulation is lifesaving in resource-poor regions and helpful in the industrialized world for clinically important dehydration.

Dietary Recommendations

Avoid carbonated beverages and fatty foods because both slow gastric emptying and worsens vomiting. Avoid sugary foods because sugar acts osmotically to draw water into the intestines worsening diarrhea. Consumption of small portions of easily digestible foods are recommended as soon as feeding is tolerated and are more effective than restricted or progressive diets in reducing duration of acute gastroenteritis because caloric intake facilitates enterocyte renewal during a bout of acute diarrhea (1). Fiber rich foods, for example, rice, potatoes, or corn, or fiber supplements, for example, psyllium or methylcellulose, are helpful because fiber absorbs water in the digestive tract and adds bulk to feces. Because transient lactase deficiency may occur, avoidance of milk products is commonly recommended (2).

Antimotility Agents

Loperamide, diphenoxylate with atropine, and dicyclomine are used to reduce urgency, bowel-movement frequency, and stool volume in diarrheal illness. Loperamide, the antimotility agent of choice for enteritis, slows peristalsis via its action on intestinal m-opiate receptors, but unlike other opiates such as diphenoxylate, it does not penetrate the central nervous system and has no potential for addiction (3). Loperamide administration with an antibiotic is safe for most causes of dysentery; it reduces diarrhea volume, and accelerates symptomatic recovery (3). Loperamide must be used in conjunction with antibiotics for dysentery, as it can inhibit clearance of the offending organism if used as solo therapy and worsen diarrheal illness (4).

Bismuth Subsalicylate

Although not as effective as loperamide in direct comparisons, bismuth subsalicylate can mitigate stool output and lessen the symptoms of diarrhea, nausea, and abdominal pain in patients with TD and other infectious causes of diarrhea, including dysentery (2). Bismuth subsalicylate's salicylate moiety has antibacterial and antisecretory effects that make it effective prophylaxis for TD. Instruct patients that bismuth subsalicylate turns the stool's color black. Administer bismuth subsalicylate with the caution to avoid inadvertent excessive ingestion and induction of salicylism.

Probiotics

Probiotics are live, nonpathogenic microorganisms, marketed for prevention and treatment of diarrhea. Yogurt is a readily available source of small amounts of probiotic bacteria such as *Lactobacillus bulgaricus* and *Streptococcus thermophilus.* Probiotics such as *Lactobacillus* GG and *Saccharomyces boulardii* are available as dietary supplements. Evidence suggests that probiotic prophylaxis results in a reduction in *C. difficile*-associated diarrhea (19). Infectious complications caused by probiotics, including sepsis with *Lactobacillus casei,* fungemia with *S. boulardii,* and liver abscesses

caused by *Lactobacillus* GG, limits probiotic use in immunosuppressed and in critically ill patients, particularly those with an indwelling vascular catheters (19).

Antibiotics

For patients with dysentery or severe TD, administration of empiric antimicrobial therapy is recommended (1), and fluoroquinolones or azithromycin are efficacious choices (eTable 112.1). For high fever, >39.4°C, or the passage of grossly bloody stools, azithromycin is recommended to treat presumed Campylobacter (4). While they should be withheld for salmonellosis because treatment prolongs carriage, administer antibiotics if the patient has risk factors for Salmonella bacteremia, which include age >65 years, immunosuppression, corticosteroid use, inflammatory bowel disease, sickle cell anemia, hemodialysis, abdominal aortic aneurysm, or prosthetic heart valve (4). The administration of antibiotics and antimotility agents is contraindicated for Shiga toxin-producing *E. coli* because antibiotics increase the risk of hemolytic uremic syndrome (2). Empiric treatment for persistent diarrhea without systemic symptoms secondary to presumed giardiasis with metronidazole is reasonable, especially if there is a history of recent travel or exposure to contaminated water because giardiasis is common and testing often fails to reveal the organism (1). Treatment of CDI can be stratified according to severity of illness, recurrence of disease, and host factors: mild-moderate, severe, or recurrent. Both oral metronidazole and vancomycin are effective for mild to moderate CDI, but vancomycin is a second-line agent because of its cost and propagation of vancomycin resistance (12). Metronidazole is less expensive, effective administered orally or intravenously, and avoids the risk of promoting vancomycin-resistant pathogens (2). Indications for using oral vancomycin to treat CDI include severe disease, metronidazole contraindications or intolerance, and inadequate response to metronidazole treatment (12). Severe CDI is defined as: intensive care unit admission, pseudomembranous colitis at endoscopy (eFig. 112.6), age >60 years, temperature >38.4°C, serum albumin <2.5 g/dL, and white blood cell count >15,000/μL

(12). Fidaxomicin, a newly available FDA approved oral antibiotic, may be superior to vancomycin in severe and recurrent CDI, but is still second line because of financial considerations (20).

Advice for Travelers

TD avoidance involves adherence to the axiom: "cook it, boil it, peel it—or forget it." In unhygienic locales, travelers must abstain from raw vegetables, fruit they have not personally peeled, unpasteurized dairy products, cooked food not served steaming hot, and tap water, including ice (21). Boiling water for 3 minutes kills most potential pathogens, which are destroyed at temperatures of 55 to 80°C, even at high altitudes (22). Oral fluid and electrolyte requirements in TD can be met in nearly all cases in otherwise healthy patients by increasing fluids and salt-containing foods in the diet (1). Bismuth subsalicylate, fluoroquinolone antibiotics, and possibly probiotics are effective prophylactic pharmacologic self-therapy of TD (21).

CRITICAL INTERVENTIONS

- Treat dehydration with appropriate fluid, salt, and caloric repletion.
- Initiate appropriate empiric antibiotic therapy for patients with dysentery.
- Appropriate dietary advice advocates early refeeding with high fiber, low fat and sugar, and nondairy diets to facilitate early enterocyte recovery and avoids exacerbating diarrheal illness.

- Antimotility agents, for example loperamide, are safe and appropriate in the setting of dysentery if administered in conjunction with appropriate antidysentery antibiotics.
- Probiotics aid in prevention of recurrent CDI.

DISPOSITION

Most ED diarrheal complaints can be managed on an outpatient basis. Consider admission if there is bloody diarrhea, severe dehydration, intractable vomiting, evidence systemic illness (e.g.,

septicemia or hemolytic uremic syndrome), and diagnostic uncertainty regarding the etiology of diarrhea, particularly if it is bloody, for consultation to rule out noninfectious, pathologic processes.

Common Pitfalls

- Anchoring diagnostic focus on viral gastroenteritis: Consider dysentery and *C. difficile* colitis if there are risk factors; also evaluate for noninfectious diarrheal etiologies, for example, inflammatory bowel disease, sprue, and small bowel obstruction.
- Ignoring examination of diarrhea: While stool cultures require laboratory processing time, point of care examination of stool for blood or leukocytes affects ED therapy and disposition.
- Omitting adjuvant diarrheal therapy: Oral rehydration solution, loperamide and bismuth subsalicylate have proven efficacy for diarrheal illness.
- Consider *C. difficile* not only in patients with colitis and diarrhea after antibiotic use but also after chemotherapy and in the community setting as well, especially if they have other risk factors for CDI (e.g., proton pump inhibitor therapy).

CHAPTER 113

Diverticular Disease

Janak K. Acharya

In the industrialized world, the increasing prevalence of diverticular disease parallels the advancing age of the population. The prevalence of diverticular disease increases from 5% in persons younger than age 40 years to 30% in those older than age 50, to 50% in those older than age 70, and to 66% in those older than age 85 years (1). Diverticulosis is equally common among men and women. The disease has widely differing prevalence rates in various geographic areas and ethnic groups (1).

The key factor in the development of diverticulosis appears to be a reduction in dietary fiber content. The pathophysiology is related to a pressure gradient between the colonic lumen and the serosa and areas of relative weakness in the bowel wall. Very high intraluminal pressure can develop within short segments of the colon. According to the Laplace law of pressures within a cylinder, pressure equals tension divided by radius. Accordingly, the descending and sigmoid colons, which have narrow lumens, have the greatest intraluminal pressures. This pressure causes herniation of diverticula at the points where the intramural vessels penetrate the circular muscle layer, usually between the mesenteric and antimesenteric taenia. Increased fiber intake enlarges the lumen size, thereby decreasing the intraluminal pressure.

The sigmoid colon is involved in more than 90% of patients with the disease, and in approximately one-half of patients it is the only segment of the bowel involved. The cecum is involved in 2%, the ascending colon and rectum in 4% each, and the transverse colon in 10%. Most individuals with diverticulosis remain asymptomatic

throughout their lives. The longer a patient has diverticulosis, the greater is the probability of complications, primarily diverticulitis and bleeding. There is no relationship, however, between the number and size of diverticula and the incidence of complications or probability of recurrent disease. The use of aspirin and other nonsteroidal anti-inflammatory drugs is an etiologic factor in the development of diverticulitis (1,2). Diverticulitis results from inflammation of diverticula, resulting in microperforation or macroperforation (abscess, fistula, peritonitis, or obstruction). Diverticular bleeding results from an arterial lesion in the vasa recta, characterized by eccentric intimal thickening, altered internal elastic lamina, and focal medial thinning (3). There is a disproportionately high tendency for diverticula on the right side of the colon to hemorrhage. One theory holds that the wider necks and domes of right-sided diverticula cause greater exposure to injurious factors than in left-sided diverticula (4). Bleeding from diverticulosis is massive in about one-fourth of patients in whom it occurs, and mandates transfusion in approximately one-third (5). Fortunately, the vast bulk of diverticular bleeding ceases spontaneously.

CLINICAL PRESENTATION

Patients with diverticulosis present to the emergency physician with three common clinical presentations: (a) acute diverticulitis, (b) lower gastrointestinal (GI) bleeding, and (c) painful diverticular disease, with mild lower left quadrant pain.

Acute Diverticulitis

Patients with acute diverticulitis classically present with abrupt onset, severe, constant left lower quadrant pain; localized tenderness; and fever, leukocytosis, or other signs of systemic toxicity. Occasionally, the pain and tenderness occur in the left upper quadrant. Patients may present with a picture of a ruptured viscus with diffuse tenderness, rebound, guarding, and diminished or absent bowel sounds. Rarely, diverticulitis may present with signs of fistulization, such as pneumaturia and draining infections of the

lower abdomen or medial aspect of the upper thigh. Diverticulitis may present atypically in immunocompromised patients, such as those with acquired immunodeficiency syndrome, renal failure, or diabetes and those receiving immunosuppressive therapy. In these patients, fever, abdominal pain, or abdominal tenderness may be absent (6). The incidence of free perforation, a rare complication in the immunocompetent, is much higher among immunocompromised patients (6–8). Although recurrence rates are similar between immunocompromised and immunocompetent patients, mortality following surgery is twice as high in the immunocompromised (9).

Lower Gastrointestinal Bleeding

Patients with diverticulosis may present with painless, massive rectal bleeding. Such bleeding is characteristically sudden, often profuse from the onset, and more frequent in older persons. The blood is usually bright or dark red, and although the patient may feel faint, initial hypotension is not common.

Painful Diverticular Disease

Although most patients with diverticulosis are asymptomatic, some develop recurrent episodes of left lower quadrant abdominal pain. The pain is usually dull, crampy, and intermittent and is often alleviated by the passage of flatus or stool. Signs of infection are absent.

DIFFERENTIAL DIAGNOSIS

Painless diverticular bleeding must be distinguished from other causes of lower GI bleeding, such as angiodysplasia, ischemic colitis, ulcerative colitis, hemorrhoids, polyps, and colonic or rectal cancer. Upper GI hemorrhage may present with rectal bleeding.

When diverticulosis presents as mild, left lower quadrant pain, it must be differentiated from irritable bowel syndrome (IBS), Crohn disease, colon cancer, ovarian pathology, and nephrolithiasis, which may present with pain radiating to the left lower quadrant.

Acute diverticulitis must be distinguished from more severe presentations of Crohn disease, ulcerative colitis, and ischemic colitis, although diverticulitis and inflammatory bowel disease may coexist. Vascular catastrophes, such as aortic rupture or dissection or mesenteric ischemia, are generally distinguished by pain out of proportion to physical findings. In women, diverticulitis that presents as a left lower quadrant mass has been misdiagnosed as a gynecologic mass (6). High fever, leukocytosis, and left lower quadrant mass should suggest perforation and abscess. These findings may also be suggested by inflammatory bowel disease, colon cancer, sigmoid volvulus, iatrogenic perforation of the rectosigmoid, or a tubo-ovarian abscess (10). Right-sided diverticulitis, a rare disease seen primarily in Asian populations, may mimic acute appendicitis (11).

ED EVALUATION

Left Lower Quadrant Pain

Historical information should focus on GI symptoms, previous similar attacks, prior diagnostic studies, and change in bowel habits. The duration of the attack, characteristics of the pain, and history of fever should also be elicited. With diverticulitis, the pain may be intermittent, crampy, and associated with nausea and vomiting. The attack may be associated with either constipation or diarrhea.

The physical examination should take careful note of the patient's temperature, pulse rate, and blood pressure. Complete abdominal, pelvic, and rectal examinations are necessary. In rare cases, tenderness may be found only on rectal examination. Palpation may reveal the outline of the sigmoid colon as a ropelike mass. Minimal tenderness and mobility point to an irritable colon; a large, sausage-like, markedly tender, fixed mass points to diverticulitis. Signs of peritonitis and the presence of a mass on pelvic and rectal examinations are important to note. A complete blood cell count (CBC) may be helpful, in that leukocytosis with a left shift is often noted in patients with diverticulitis.

Although acute diverticulitis can be diagnosed solely on clinical grounds, confirmatory imaging is necessary for all but mild, recurrent cases. Abdominal and chest radiographs may show obstruction or free air, but computed tomography (CT) is the most cost-effective test (12). CT allows evaluation of vascular structures, estimates the extent of diverticulitis, allows possible percutaneous drainage, and is less invasive than traditional contrast enema evaluation (1) (Fig. 113.1). The method also has a greater sensitivity than contrast enema (13). If CT is unavailable, contrast enema remains a safe and effective option (5,8). A few centers have reported high accuracy in diagnosing diverticulitis with ultrasonography (5,8,14). Ultrasonographic findings seen in diverticulitis include the following: hypoechoic, tender, thickened colonic segment; visible diverticula; and increased echogenicity surrounding the diseased colon (12). Sigmoidoscopy should be avoided in patients with acute diverticulitis.

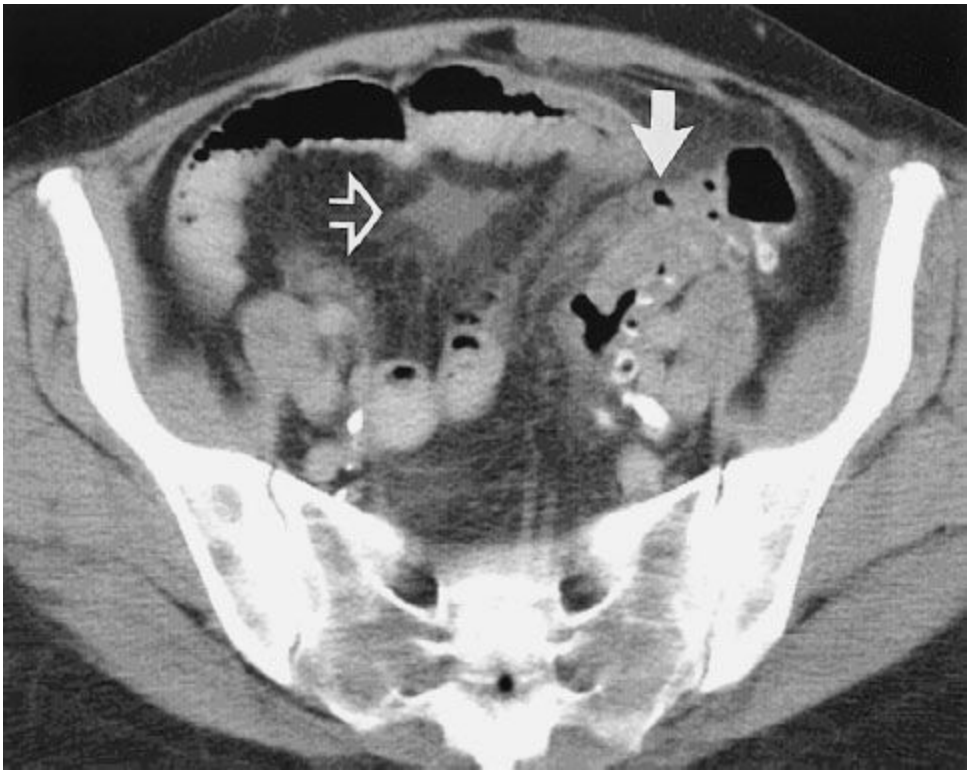

FIGURE 113.1 Sigmoid diverticulitis. CT scan shows multiple sigmoid diverticula, inflammatory stranding (*arrow*), and a small amount of free fluid (*open arrow*). (From Harris JH, Harris WH, eds.

The Radiology of Emergency Medicine, 4th ed. New York, NY: Lippincott; 2000:651.)

The Hinchey classification scheme was originally used to describe intraoperative findings associated with diverticulitis (15). Stage 1 and 2 represent confined pericolic or perimesenteric abscesses and carry a 5% mortality. Stage 3 disease presents with peritonitis secondary to rupture of a peridiverticular abscess and has a 13% mortality. Stage 4 diverticulitis or free rupture of an uninflamed diverticulum, causing fecal contamination of the peritoneum, is rare but carries a 43% mortality (16). CT scanning can be used to risk stratify patients according to their Hinchey classification and facilitate appropriate management and disposition.

Lower Gastrointestinal Bleeding

The history should focus on the onset, color, amount, and frequency of bloody bowel movements. A history of previous attacks, bleeding tendencies, and bowel habits is important. Hemodynamic instability should be assessed (blood pressure, pulse, and orthostatic changes). The abdominal examination should focus on areas of tenderness and the presence or absence of a mass. The rectum should be palpated for masses, and the color of the blood in the rectal vault should be examined. Nasogastric intubation may indicate upper GI hemorrhage, particularly if the source is proximal to the duodenum. If there is brisk and bright red bleeding, anoscopy can exclude anorectal causes such as internal hemorrhoids. Laboratory studies should include a CBC to help estimate the amount of blood loss, and a type and screen if transfusion is considered.

KEY TESTING

- Basic laboratory studies
- CT scan of the abdomen and pelvis with IV contrast

ED MANAGEMENT

Acute Diverticulitis

For the patient with acute diverticulitis, an intravenous line should be started, blood and urine specimens should be collected, and intravenous antibiotics begun. Antibiotics should target gram-negative rods and anaerobic bacteria. Effective single agents include imipenem/cilastatin (0.5 to 1 g), ampicillin/sulbactam (3 g), or piperacillin/tazobactam (3.375 g), and an effective traditional triple-therapy regimen consists of ampicillin (0.5 g), gentamycin (1.5 mg/kg), and metronidazole (0.5 to 1 g) (1,12). Outpatient management for mild cases may include a combination of metronidazole and either trimethoprim-sulfamethoxazole or ciprofloxacin, or monotherapy with amoxicillin-clavulanate. Supportive management of uncomplicated diverticulitis without antibiotics has been evaluated, with data showing similar recovery times and recurrence rates but with a higher rate of complications (17). Early surgical consultation is indicated in patients with peritonitis or radiographic evidence of large abscess or free rupture.

Diverticular Bleeding

For the patient with massive lower GI bleeding, two large-bore intravenous lines (16 gauge or larger) should be inserted. A blood specimen should be obtained and sent for type and crossmatch for 4 to 6 units of blood. A Foley catheter should be placed. Lactated Ringer solution or normal saline should then be infused in accordance with the patient's vital signs and cardiac status. If the patient remains hypovolemic after 2 L of crystalloid infusion, blood transfusion should be considered. Fluid resuscitation should be aimed at restoring urine output to a rate of approximately 1 mL/kg/h.

Painful Diverticular Disease

For the patient with left lower quadrant pain but without signs of acute diverticulitis or bleeding, institution of a high-fiber diet is effective in relieving pain. There is an increased incidence of IBS

following acute diverticulitis and an increased association of diverticular disease in patients with IBS (7). Anticholinergic agents have long been used, but their efficacy remains unproven. Routine colonoscopy following uncomplicated diverticulitis in the absence of other risk factors has not identified a higher incidence of malignancy than in the general population (11).

The use of probiotics such as *Lactobacillus casei,* alone or in combination with mesalamine, has been shown to prevent recurrence of uncomplicated diverticular disease (18). Mesalamine, in addition, has been shown to reduce the GI symptoms following an acute attack of diverticulitis as compared with placebo or a probiotic-mesalamine combination (19).

CRITICAL INTERVENTIONS

- Administer parenteral antibiotic therapy and analgesics for those with acute severe diverticulitis.
- Provide adequate fluid and blood component therapy for patients with significant lower GI bleeding.
- Obtain early surgical consultation in patients with peritonitis, abscess, or free rupture.

DISPOSITION

Patients with severe acute diverticulitis (Hinchey stage 2 or greater) and those with gross lower GI bleeding must be admitted. Patients with diverticulitis complicated by abscesses more than 4 cm in diameter that are not amenable to percutaneous drainage, as well as those with fistula formation, obstruction, or localized peritonitis, should be admitted to a surgical service. Patients with clinical or radiographic signs of free rupture, fecal contamination with generalized peritonitis (Hinchey stage 3 or 4), or massive lower GI hemorrhage warrant emergent surgical evaluation for operative management. Septic patients, those with significant comorbidities, and those with massive GI bleeding should be admitted to an intensive care unit.

Outpatient management should be limited to immunocompetent patients with mild uncomplicated diverticulitis (Hinchey stage 1), or with diverticulosis with minimal bleeding. Immunocompromised patients and renal-failure patients with diverticulitis should be admitted despite benign-appearing presentations.

Common Pitfalls

- Failure to appreciate the severity of illness in immunocompromised patients. These patients have a higher incidence of free perforation, failure of medical therapy, and postoperative morbidity and mortality (6,8).
- Although less frequently encountered in patients younger than age 40 years, diverticulitis is relatively more likely to be complicated and require surgery in younger patients than in older patients (20,21).

CHAPTER 114 Anorectal Disorders

Wendy C. Coates

A variety of anorectal conditions can prompt a visit to the emergency department (ED). These conditions may be isolated and temporary or may signal an underlying systemic disease. Great sensitivity is required in dealing with patients who have problems in this area, as they may be embarrassed to share details with the healthcare provider.

The rectum originates at the end of the sigmoid colon and stores stool until a convenient time for defecation. The anal canal is the terminal portion of the digestive system and is approximately 4 cm in length. At the dentate line of the anal canal, the epithelium changes from the columnar epithelium of the intestine to a modified squamous epithelium. Several glands reside in this area to provide lubrication for the easy passage of stool. Fecal continence is maintained by a cooperation of both voluntary and involuntary muscle sphincters.

CLINICAL PRESENTATION

Patients with anorectal conditions may present with a variety of symptoms, including pain, itching, swelling, bleeding, fever, mass, or discharge, depending upon the specific condition (Fig. 114.1). Many patients present with a chief complaint of “hemorrhoids” to represent any anorectal condition. Careful questioning can elucidate the actual diagnosis.

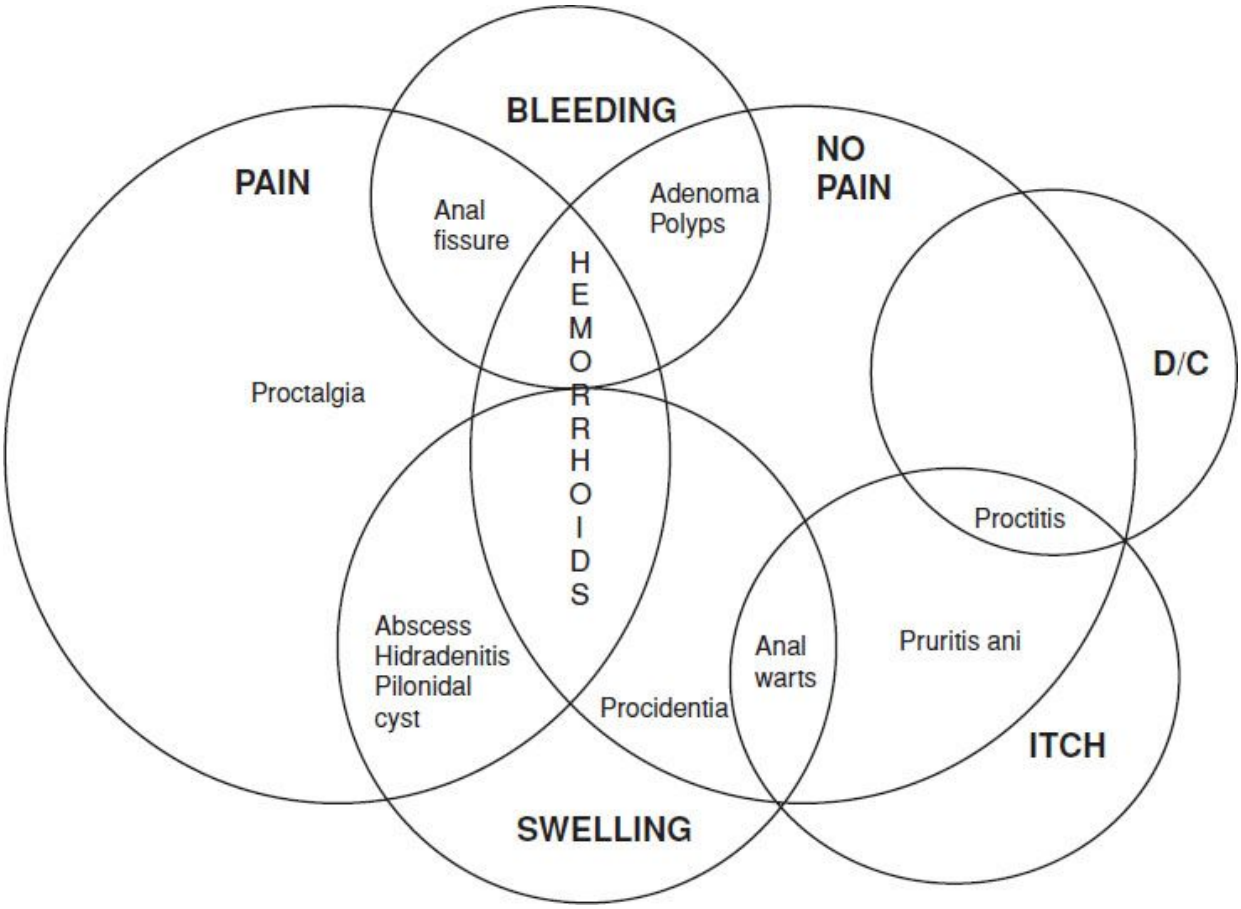

FIGURE 114.1 Anorectal complaints algorithm (Venn diagram).

Painful Swelling

Anorectal abscess is a common acute infection involving the anorectum. The etiology may be the entrapment of mucous and bacteria in the glands of the anal crypts. When deep abscesses rupture, a fistulous tract forms. A complex network of abscesses and fistulas may evolve if the acute condition goes untreated. Abscesses are named according to their location (Fig. 114.2).

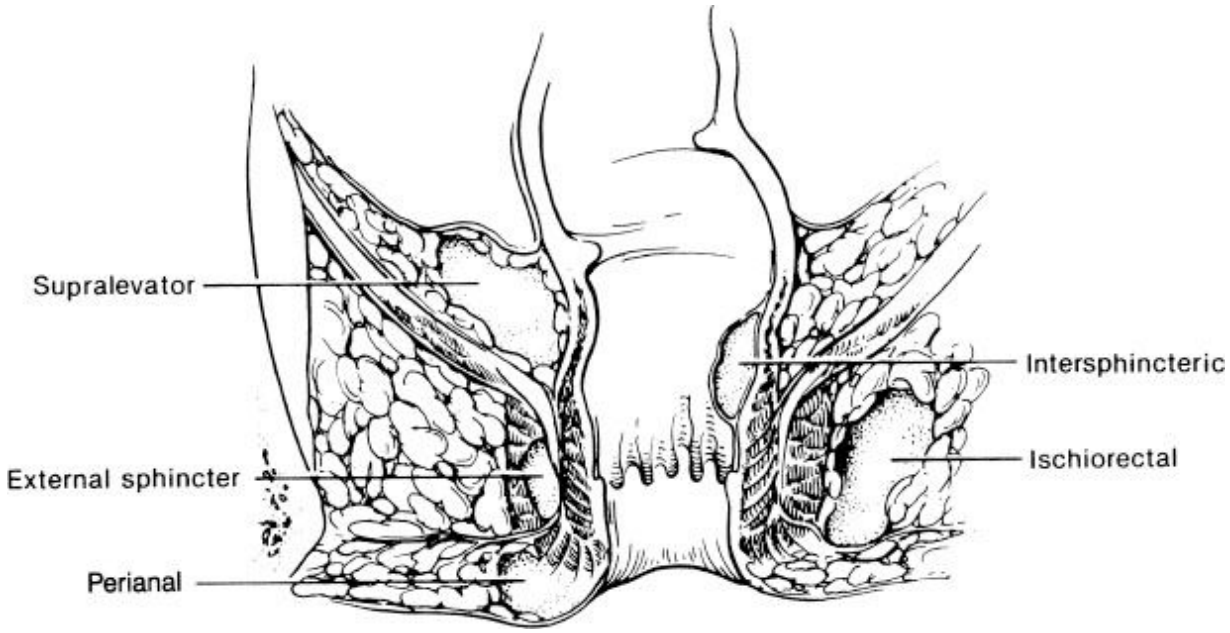

FIGURE 114.2 Anorectal abscesses.

Symptoms and sequelae vary depending on the depth and natural ability of the abscess to drain. The clinical presentation depends on the depth and location of the abscess. Superficial (*perianal*) abscesses usually present as tender swellings near the anus. Foul-smelling pus may drain from spontaneously ruptured abscesses. Deep abscesses may cause pain within the rectal cavity or pelvis and progress to a systemic infection. Fistulous tracts may develop and may open directly into the anorectum or through the skin of the buttocks (1,2).

A *pilonidal abscess* (cyst) is a painful, indurated swelling that occurs in the presacral midline (3). Sinus tracts may develop and open into the surrounding skin of the buttocks. Afflicted patients may also demonstrate hair in the midline in other locations of their bodies, such as the eyebrows.

Hidradenitis suppurativa is caused by an infection to the apocrine glands and is related to poor hygiene or an underlying disease, such as diabetes mellitus or predisposition to the condition. Patients frequently have fever and leukocytosis and may have similar lesions in the axilla or sternum (4).

Painful Bleeding

Anal fissures produce sudden, sharp, tearing pain at the anal orifice during defecation. The patient generally reports seeing bright-red blood on the tissue. Most fissures occur in the midline. Ectatic fissures often suggest underlying disease. Fissures are the most common pediatric anorectal complaint. *Hemorrhoids* can present in a variety of ways, but the classic presentation is painful bright-red blood that coats the stool. A variety of factors predispose patients to develop hemorrhoids. Most often, the condition is self-limited and is caused by frequent diarrhea, prolonged sitting, low-fiber diet, and pregnancy and may be exacerbated by underlying medical conditions such as obesity, portal hypertension, or bleeding disorders. Patients may complain of anorectal swelling with moist discharge or intense unbearable pain and swelling (1,5,6).

Without Bleeding or Swelling

Some patients have rectal pain that does not have any of the pathophysiologic mechanisms described. Their pain may be of sudden or gradual onset and takes on different characteristics depending on the cause. Before making a diagnosis of the two common entities, *levator syndrome* or *proctalgia fugax,* it is important to exclude other causes of pain.

Painless Conditions

Patients with *rectal prolapse* (*procidentia*) present with a large externally protruding mass. The presentation may be preceded by defecation, sneezing, or coughing. Most patients are in the extremes of age. A foul odor may be present (7).

Anal warts (*condylomata acuminata*) may also present as a painless swelling at the anal opening. Patients generally report concurrent itching and often have had contact with another individual with a similar condition. Genital warts are caused by the human papilloma virus. A sexual history highlighting the role of the anus in intercourse is essential. Children with genital warts may have contracted them as a result of sexual assault or simply by the

transmission of the virus on the hands of the person changing their diaper. Other causes of perianal itching (*pruritus ani*) range from dietary habits (caffeine, citrus, and spicy foods) or drugs (steroids, tetracycline, and colchicine) to hygiene and underlying skin conditions (pinworms and psoriasis). Patients frequently complain of an insurmountable urge to scratch, and the symptoms typically are worse in the warm months. Underlying anorectal disease (fistula, fissures, proctitis, and prolapsed hemorrhoids) may present as pruritus ani.

Patients who have proctitis, an inflammatory condition of the rectum, may present with a sensation of internal fullness accompanied by a change in bowel habits such as constipation or diarrhea. This can be caused by infections, sexually transmitted diseases (STDs), antibiotics, radiation, or inflammatory bowel disease. Occasionally, proctitis may present with pain or discharge.

Foreign Bodies

Rectal foreign bodies are covered more specifically in Chapter 115.

DIFFERENTIAL DIAGNOSIS

Painful swellings of the anorectum include hemorrhoids, abscesses, pilonidal disease, and hidradenitis suppurativa (Fig. 114.1). The presence of pus or fever suggests an abscess. For many patients with abscesses and fistulas, their problem is recurrent. A specialized abscess that is lined with epithelium and is found in the presacral area is a pilonidal cyst. This condition occurs more frequently in young men and reflects a midline defect in which debris from hair follicles and glandular secretions collects and becomes indurated.

Patients who present with painful bleeding are likely to have hemorrhoids or an anal fissure. Fissures tend to present as sudden, sharp, and tearing pain with subsequent burning, whereas hemorrhoids generally have a more gradual onset and a more varied course. Hemorrhoids can mimic any anorectal condition. A thorough history and physical examination can confirm an ultimate diagnosis of hemorrhoids.

Rectal pain that occurs from a cause other than those already mentioned may be of neuromuscular etiology. Levator ani syndrome is distinguished by its gradual onset and persistence as a dull pain that is exacerbated by defecation. Patients with sudden, intense spasmodic pain in the rectal area may have proctalgia fugax. This condition is frequently associated with the "type A" personality but may occur in any patient. Its onset is often during intercourse, urination, defecation, or sleep (8,9).

Patients who present with rectal bleeding that is unaccompanied by pain may have internal or external hemorrhoids that are neither thrombosed nor lodged in the sphincter to produce pain. These patients typically have intermittent bright-red blood that coats the stool. Patients with bright-red blood mixed in with the stool should be evaluated for brisk upper or lower gastrointestinal (GI) bleeding. Patients whose source of bleeding is of uncertain etiology should be evaluated for rectal cancer or polyps.

Procidentia may be complete (all layers of the rectum protrude) or incomplete (mucosal layer only). It is important to distinguish this from prolapsed internal hemorrhoids and rectal masses. In young children, the diagnosis of cystic fibrosis is suspected (7).

Patients with pruritus ani should be examined closely and questioned about potential sources of their condition. Other diseases to consider in the differential diagnosis of condylomata acuminata are squamous cell carcinoma or secondary syphilis (condyloma latum), which is flatter.

Proctitis should be considered in patients who have undergone radiotherapy or recent antibiotic therapy, who utilize the rectum for sexual gratification, who have introduced foreign objects or lubricants into the rectum, or who have underlying inflammatory bowel disease.

ED EVALUATION

A thorough history and physical examination are important in distinguishing common anorectal complaints (see Fig. 114.1) (9). Local symptoms such as pain, bleeding, discharge, and itching are the foundation for the history. Questions about underlying GI

conditions (e.g., Crohn disease, inflammatory bowel disease, and GI cancer); systemic illnesses (e.g., diabetes mellitus, AIDS, and cancer); and trauma provide clues about the etiology of the symptoms. Some individuals use the rectum during intercourse and others introduce foreign objects that they cannot retrieve.

The physical examination should begin with an observation of hygiene, structural integrity, and the presence of lesions, blood, or discharge. A digital rectal examination (DRE) can assess sphincter tone and can reveal masses in the anorectum or adjacent structures. Any stool remaining on the examiner's glove can be used to check for occult blood. Finally, anoscopy can be performed to visualize lesions in the anal canal.

Abscesses are defined by their location. *Perianal abscesses* are adjacent to the anal outlet and are superficial in nature. Most patients are afebrile. Visual inspection of the perianal area may reveal pus or a fluctuant mass with or without surrounding erythema. *Ischiorectal abscesses* are exterior to the sphincter muscles and are located in the buttocks. Patients frequently cite severe buttock pain. Deeper ischiorectal abscesses may cause fever and leukocytosis. *Intersphincteric abscesses* form above the external sphincter and below the levator ani muscles. They may appear as a protrusion into the rectum and may be confused with inflamed hemorrhoids upon anoscopy. *Supralevator abscesses* are uncommon and are located deep to the levator ani muscles. There is an increased predominance in patients who are immunocompromised and in those with associated conditions (e.g., Crohn disease, pelvic inflammatory disease, or diverticulitis). Diagnosis relies on a high index of suspicion in patients with pelvic pain, fever, and leukocytosis. DRE may reveal a fistulous outflow track in the anal canal that may be palpable (1,2). If the extent of the abscess cannot be determined by physical exam, CT scan may be helpful.

Patients with a painful swelling in the presacral area with associated openings from sinus tracts have pilonidal disease. They are usually fluctuant and tender and may spontaneously begin to drain hairy pus. Extension of the disease to the entire presacrum is possible (3). Multiple infected openings that are not limited to the

presacral area may indicate hidradenitis suppurativa. Local lymphadenopathy is a common finding, and many patients are febrile and have an elevated white blood cell count (4).

Anal fissures are suspected when there is a sudden pain near the anus and bright-red blood on the tissue. Most benign fissures are located in the anoderm at the posterior midline. Although women may have fissures in the anterior midline, fissures in other locations often herald a serious underlying disease (e.g., Crohn disease, leukemia, tuberculosis, or human immunodeficiency virus [HIV]). The acute appearance of the fissure is similar to that of a laceration of the anoderm. Chronic changes may occur if a fissure is left untreated and include the development of tissue edema, a sentinel pile (hypertrophic and edematous skin), and skin tags upon resolution (10).

Hemorrhoids may be classified as external or internal. External hemorrhoids are close to the anal orifice and are covered with anoderm. Careful inspection reveals a coloring of the epithelium that is similar to that of surrounding skin. Patients may have perianal skin tags that have resulted from prior episodes of external hemorrhoids. A hard, bluish mass in the location of an external hemorrhoid denotes a thrombosed external hemorrhoid (5,6).

Internal hemorrhoids originate superior to the dentate line and are supplied by the superior hemorrhoidal vessels. Their covering appears mucosal in nature and does not resemble surrounding skin at all. A classification system of four grades has been developed. Grade I internal hemorrhoids produce symptoms of fullness and pain with bleeding but do not exit the anus at any time. Grade II internal hemorrhoids prolapse during defecation but spontaneously retract when straining ceases. Grade III internal hemorrhoids prolapse during defecation and require manual replacement. Grade IV internal hemorrhoids prolapse at any time, cannot be reduced, and may thrombose or become gangrenous (5,6).

To delineate the cause of rectal pain that does not fit into one of the categories described previously, one must first rule out a serious underlying condition, including cauda equina syndrome, cancer, or endometriosis. The diagnosis of proctalgia fugax or levator ani

syndrome is typically based on historical findings. If the patient tolerates a rectal examination, the levator ani muscles may be tender to palpation in levator ani syndrome (11).

Evaluation of patients with painless rectal bleeding includes DRE with subsequent hemoccult testing. If desired, anoscopy can be performed to visualize hemorrhoids or potential erosions in the mucosal wall. Procidentia is identified by noting concentric rings of mucosal tissue that may be ulcerated and is associated with a mucoid discharge or is stained with stool. If all layers are involved in the prolapse, they can be identified as well (12).

Anal warts appear as papilliform lesions that often coalesce at the anus and may extend to the anal canal. Direct irritation to the warts may induce minimal bleeding. A detailed sexual history may reveal that the patient is HIV-positive or has concurrent STDs. Evaluation of pruritus ani begins with a detailed history and physical examination.

Proctitis of infectious etiology is most often caused by organisms responsible for STDs in persons who have receptive anal intercourse. Common organisms are herpes simplex (HSV), gonorrhea, and chlamydia. Patients may present with diarrhea or constipation and may have a mucopurulent discharge from the rectum. Occasionally, they may have manifestations of systemic disease, including fever, chills, and leukocytosis. These patients may also have a component of allergic proctitis that results from the introduction of foreign substances into the rectum. For example, lubricants, erotic objects, and soaps may irritate the mucosa or produce small tears, leading to inflammatory changes. Patients with underlying inflammatory bowel disease may experience periodic inflammation of the rectum and have a mucoid discharge, constipation, or diarrhea, indicative of proctitis. Radiation proctitis occurs most often in cancer patients who have undergone focused irradiation to the pelvic and lower GI systems and may present with diarrhea, pain, tenesmus, fistula-in-ano, or rectal strictures (13).

KEY TESTING

- Digital rectal examination
- Anoscopy as needed

ED MANAGEMENT

General treatment of most anorectal conditions focuses on maintaining good hygiene and producing stool that is easy to pass. This can be accomplished by following the WASH regimen (Fig. 114.3).

W	Warm water	Promotes anal sphincter relaxation and good hygiene
A	Analgesics	Provides symptomatic relief from pain
S	Stool softener	Makes stool easier to traverse anal opening
H	High-fiber diet	Produces stool with bulk and air and reduces transit time

FIGURE 114.3 The WASH regimen.

Perianal abscesses can usually be incised and drained in the ED with good local anesthesia. Exceptions include abscesses in children and in patients who are immunocompromised (14). Superficial ischiorectal abscesses may be incised and drained via a skin incision on the buttocks. However, deeper perirectal abscesses generally require drainage in the operating room (OR) under anesthesia. Antibiotics should be considered, especially if there is surrounding cellulitis, fever, or leukocytosis. Drainage of intersphincteric and supralevator abscesses takes place in the OR. If a fistula is palpated in the anorectum or along the surface of the buttocks, it should be left intact to prevent the inadvertent puncture and subsequent extension of the fistulous network. Definitive treatment is a fistulectomy in the OR, although fibrin glue has been tried successfully as a less-invasive management strategy (2,10). Patients with a fistula without evidence of an abscess may have Crohn disease, cancer, or tuberculosis. These patients should be referred appropriately when a fistula is detected.

The ED treatment of an isolated pilonidal cyst begins with its identification in the presacrum. Incision and drainage should be done vertically and lateral to the midline to prevent further scarring and inflammation. Antibiotics may be used as an adjunct to incision and

drainage in patients who have accompanying cellulitis. Patients with extensive spread of pilonidal disease may be referred to surgery to consider wide excision (3).

Treatment of hidradenitis suppurativa begins with attention to improved hygiene. Incision and drainage of pustules may provide symptomatic relief, but a broad-spectrum antibiotic may be necessary to diminish the severity of the exacerbation of this condition (4).

Anal fissures should be treated acutely by following the WASH regimen so that the stool is easier to pass. Application of topical nitroglycerin ointment (0.4%) twice daily may alleviate symptoms. Short-term application of topical nifedipine gel (0.2%) with lidocaine (1.5%) alleviates symptoms and may promote healing. Finally, the injection of botulinum toxin (2.5 to 5.0 million units) into the muscular anal sphincter produces rapid relief from the fissure but may cause temporary fecal incontinence (10). ED management of external hemorrhoids is to follow the WASH regimen. Topical creams available over the counter may provide symptomatic relief but do not alter the course of the disease. Prolonged use of local anesthetic or steroid creams can lead to local skin irritation and breakdown. Thrombosed external hemorrhoids may be excised in the ED by anesthetizing the skin and completely removing the clot and its overlying tissue. The use of excision rather than incision and drainage prevents the formation of perianal skin tags. It is critical to distinguish between external and internal thrombosed hemorrhoids before attempting an excision (15).

Internal hemorrhoids should be managed with the WASH regimen. Warm water may produce enough anal dilation to reduce prolapsed internal hemorrhoids. Pain medications may be administered, but care should be taken to prevent constipation. Thrombosed fourth-degree internal hemorrhoids are generally managed operatively. Gangrenous hemorrhoids require prompt surgical treatment (6). If a benign source of rectal bleeding (e.g., internal hemorrhoid) cannot be identified, the patient should be referred to a specialist for endoscopic evaluation of the rectum and colon (9).

Treatment of levator ani syndrome focuses on the relaxation of the involved muscles using benzodiazepines, topical nitrates, or warm water baths (8). In addition to these regimens, patients who have proctalgia fugax have reported relief when applying upward pressure with their fist against the anus.

Procidentia can be managed in the ED or the OR by attempting reduction. Gauze moistened with saline can be applied to the protruding rectum, which can be reinserted through the anal verge. In most cases, sedation is required. If the reduction is successful, conservative management using the WASH regimen may prevent recurrence, especially in children (7). However, it is likely that a more permanent cure is surgical to strengthen the muscles that enabled the rectum to prolapse through the anus (12).

Once anal warts have been diagnosed, the cause should be identified. A full sexual history should be taken, and the patient should be referred for HIV testing. Children should be referred for testing for sexual abuse if there is not a credible source for inadvertent transmission of the virus during routine care. Treatment can be done as an outpatient with 0.5% podofilox gel for isolated condylomas. Diffuse disease requires frequent visits to the physician for application of podophyllin resin, excision, or other removal techniques.

Treatment of pruritus ani is directed at the particular cause, if possible. It may include advice on how to maintain proper hygiene or alter the diet to reduce intake of the offending food or beverage. If an anorectal problem is the cause, treating the underlying condition is likely to improve the symptoms. Medical conditions, both dermatologic and systemic, should be treated appropriately. For idiopathic pruritus ani, symptoms may be alleviated by a short course of topical 1% hydrocortisone ointment (16).

ED treatment of proctitis is aimed at relieving symptoms and is often simply supportive. Infectious proctitis should be treated with a regimen that covers organisms commonly associated with STDs. At the time of evaluation, the identity of the offending organism is usually unknown, and it is helpful to obtain cultures to direct future therapy. The suggested empiric antibiotic regimen is a single dose of

ceftriaxone 125 mg intramuscularly, plus doxycycline 100 mg orally for 7 days. If ulcerative lesions are seen on anoscopy or in the perianal area, an infection with HSV is possible. In addition to the above regimen, treatment with acyclovir 800 mg orally for 7 to 10 days is indicated (17). These patients should be referred for HIV and syphilis testing.

Treatment for radiation proctitis is aimed at relieving symptoms. In addition to supportive therapy, patients can sometimes benefit from botulinum toxin injection, oral sucralfate, or hyperbaric oxygen therapy or may be referred to a proctologist for sclerosing therapy (18).

Some rectal foreign bodies may be removed with adequate sedation in the ED, as described in Chapter 115. Patients who have anorectal foreign bodies, trauma, or proctitis should be questioned about the possibility of sexual assault.

CRITICAL INTERVENTIONS

- Initiate antibiotics and surgical consultation for patients with a suspected deep perirectal abscess and systemic signs of infection.
- Stabilize patients with acute blood loss of anorectal origin.
- Search for signs of complications (hemorrhage and perforation) in patients with rectal foreign bodies. Consider sexual assault.

DISPOSITION

Most patients with limited anorectal complaints can be discharged safely from the ED and told to follow the WASH regimen (see Fig. 114.3). For abscesses that cannot be drained easily in the ED, operative management is indicated. Those who display signs of systemic infection, such as fever and leukocytosis, should receive prompt surgical intervention. Several surgical options are available for repair of hemorrhoids, and an appropriate referral should be made. Immediate surgical referral should be made for gangrenous fourth-degree internal hemorrhoids. For patients whose genital warts are widespread, referral for repetitive topical treatment or surgical management can be made. Patients with rectal foreign bodies can be

discharged if the removal was routine and uncomplicated. Many require admission for surgical intervention.

Common Pitfalls

- Do not assume that a patient complaining of "hemorrhoids" actually has them. Consider underlying disease with an anorectal component that may be described as "hemorrhoids" by the patient.
- Mistaking a thrombosed internal hemorrhoid for an external one and excising it.
- Probing anorectal fistulas in the ED.

CHAPTER 115 Gastrointestinal Foreign Bodies

Valerie C. Norton

Gastrointestinal (GI) foreign bodies present a diverse set of challenges. Presentations range from the obvious to the occult and from the benign to the life-threatening. Management options range from watchful waiting to emergent endoscopy or surgery.

Children account for about 80% of cases of ingested foreign bodies (see Chapter 273) and tend to ingest coins, toys, and other small objects left within their reach. Adult patients at highest risk include:

- psychiatric patients (who may swallow unusual objects intentionally)
- prisoners (usually seeking secondary gain through release to a hospital)
- patients with mental disability or impairment
- intoxicated patients
- those with underlying esophageal abnormalities such as strictures
- denture wearers (due to reduced sensation of the palate) (1)

Ingested foreign bodies frequently become lodged in the esophagus, often requiring urgent removal. Much more rarely, objects fail to pass the pylorus or the ileocecal valve. More than 80% of ingested foreign bodies that pass into the stomach will traverse the rest of the gut uneventfully (2). Objects longer than 6 cm or wider than 2.5 are less likely to pass spontaneously and may have to be retrieved endoscopically if still in the stomach or

proximal duodenum. Objects that are more likely to cause perforation include sharp objects such as pins or toothpicks, animal bones, button batteries, and magnets. However, many of these will still pass without sequelae if they make it past the esophagus (1,3).

Of primary concern are objects lodged in the esophagus, because these are at highest risk for complications such as mucosal erosions, perforation, or airway compromise. Objects typically lodge at the level of the cricopharyngeus muscle, the level of the aortic arch, or the lower esophageal sphincter. High esophageal impactions are most common in children; adults most often have obstructions at the lower esophageal sphincter (2). Food boluses, particularly meat, are the most common cause of esophageal impaction in adults, and often result from underlying esophageal pathology, usually a stricture (1). Foreign bodies with toxic contents, such as button batteries and packages of cocaine, represent special cases (see Chapters 254 and 329). A button battery lodged in the esophagus is a true emergency requiring immediate endoscopic removal, whereas endoscopy is contraindicated for drug packets because of the risk of rupturing the packet (1,4).

Rectal foreign bodies are usually the result of sexual misadventure or assault, though occasionally a patient will present with an ingested foreign body, such as an animal bone or toothpick, that passes through the entire gut only to become lodged in the rectum (5,6). Men are at least 28 times more likely than women to present with rectal foreign bodies (2). Objects inserted into the rectum range from vibrators and vegetables to drugs or other contraband. Many objects are not visible on x-ray, though most are low-lying and palpable on rectal examination. Mucosal lacerations and rectal perforations are fairly common, especially in assault victims, and may result in life-threatening sepsis.

CLINICAL PRESENTATION

Healthy adults with ingested foreign bodies usually give a clear history of the inciting incident and may report a foreign body sensation if the object is lodged in the upper esophagus or

hypopharynx where somatic nerve endings are present. Scratches or abrasions to the hypopharynx cause a foreign body sensation as well, and endoscopy shows no pathology in about 75% of patients who think they have a foreign body in the throat (2). If a meat bolus or other object is impacted in the mid- to lower esophagus, patients usually complain of more visceral-type chest pain, odynophagia, and difficulty handling secretions. Objects that have passed into the stomach or beyond frequently cause no symptoms, unless obstruction or perforation has ensued.

Small children and adults with impaired mentation may not give a clear history of foreign body ingestion. Clinicians may have to rely on symptoms of obstruction, such as drooling if the object is in the esophagus, or vomiting and distension if it is impacted below the stomach. Patients may also present with GI bleeding or signs and symptoms of peritonitis due to perforation. Small children often display indirect symptoms such as gagging, choking, drooling, refusal to eat, irritability, blood-tinged saliva, stridor, wheezing, or respiratory distress. Esophageal foreign bodies can cause respiratory symptoms in small children because the object often compresses the adjacent trachea or causes aspiration of saliva.

Patients with rectal foreign bodies usually state clearly that something is in the rectum, though they may be reluctant to report how it got there. Patients or their partners have often made multiple attempts to remove the object (2). Some patients may be unaware of the object if intoxicated at the time of insertion, or may be too embarrassed to admit to it, complaining instead of rectal pain or bleeding. Patients with extraperitoneal rectal perforation may present with sepsis, whereas those with intraperitoneal perforation present with peritonitis.

DIFFERENTIAL DIAGNOSIS

In the absence of a history of ingestion or insertion of a foreign body, the differential diagnosis is broad. Other organ systems may initially be the focus of concern, because esophageal pain can mimic cardiac angina, and respiratory symptoms may be mistaken for

croup, asthma, or allergic reaction. The possibility of foreign body ingestion or aspiration should always be considered in small children with new-onset wheezing, especially if it does not respond to bronchodilators (4).

Subacute and chronic presentations do not rule out foreign bodies. There are many reports of patients with objects dwelling in the stomach or intestines for years before causing symptoms. Esophageal foreign bodies have been impacted for a month or more in some children without serious sequelae (7). Even when there is a clear-cut history of foreign body ingestion or insertion, other unsuspected pathology may be present, such as a second foreign body, a mucosal laceration, perforation of the esophagus or the rectum, or underlying esophageal disease (4,5).

ED EVALUATION

Initial assessment should aim at immediate detection and treatment of those with airway compromise, sepsis, or perforation. In more stable patients, the examiner should look for signs of esophageal obstruction such as drooling or the inability to swallow secretions, signs of lower intestinal obstruction, or evidence of GI bleeding. In the majority of patients with upper GI foreign bodies, the physical examination will be unrevealing. By contrast, rectal foreign bodies are usually palpable on rectal examination. Some authors advise against a digital rectal examination prior to obtaining radiographs, because the examiners may injure themselves if an unexpectedly sharp object is present (2).

Imaging studies are often helpful, though a negative study does not rule out a radiolucent foreign body. For small fish bones lodged in the hypopharynx, computerized tomography (CT) has been found to be more sensitive than plain films (8). Although chicken bones are often visible on plain films (2), some authors report poor sensitivity with plain films and recommend CT for any suspected animal bone above the diaphragm (1,2). For suspected esophageal foreign bodies, both anteroposterior and lateral radiographs of the neck and chest are recommended to avoid missing a second foreign

body located behind the first, or lower in the esophagus (1,2,9,10). Both views also help to rule out a tracheobronchial foreign body. Flat objects in the esophagus, such as coins, typically appear “en face” on anteroposterior view because the easily compressible esophagus typically lies somewhat flattened between the trachea and the spine. Tracheal coins, by contrast, typically appear “on end” on anteroposterior views, because the more rigid tracheal rings have their widest diameter in the sagittal plane (2). Radiographic evidence of esophageal edema on a lateral view indicates a prolonged impaction and the need for urgent endoscopic evaluation (4,7,9,11).

Imaging with oral contrast should not be done for suspected foreign bodies in the esophagus. In cases with negative imaging but high clinical suspicion, patients should go straight to endoscopy, as oral contrast material may increase the risk of aspiration or obscure endoscopic visualization of the object (1,12).

Some authors have advocated the use of a hand-held metal detector in lieu of plain films to evaluate the presence and location of metal foreign bodies (13,14). However, studies published to date indicate that hand-held metal detectors are not as sensitive as radiographs. Small objects with low metallic mass can be missed, and even coins are occasionally missed or incorrectly localized. More importantly, metal detectors cannot distinguish between sharp and blunt objects, and cannot reliably make the crucial distinction between the lower esophagus and the stomach when localizing an object (13,14).

Objects below the esophagus may be evaluated with standard plain films or contrast radiography if necessary. In most cases the primary reasons to obtain radiographs are to determine whether an ingested object has passed beyond the esophagus and whether the object has any physical characteristics that will make passage or extraction more difficult, such as a sharp edge.

KEY TESTING

- Plain films (AP and lateral) will identify most inorganic items likely to be ingested by children, such as coins, batteries, or toys.
- CT is more sensitive for fish bones in the hypopharynx and may be helpful for other smaller esophageal foreign bodies such as small chicken bones, glass, or plastic.
- Patients with suspected esophageal foreign body and persistent symptoms should undergo endoscopy even in the setting of negative imaging.

ED MANAGEMENT

Patients with signs of airway compromise require definitive airway management and emergent endoscopic consultation to remove the foreign body. Those with signs of hollow viscus perforation, massive bleeding, or sepsis require immediate resuscitation, intravenous antibiotics, and emergent surgical consultation.

The management of stable patients depends on the type, location, and duration of impaction of the foreign body. Management guidelines are summarized in Figure 115.1.

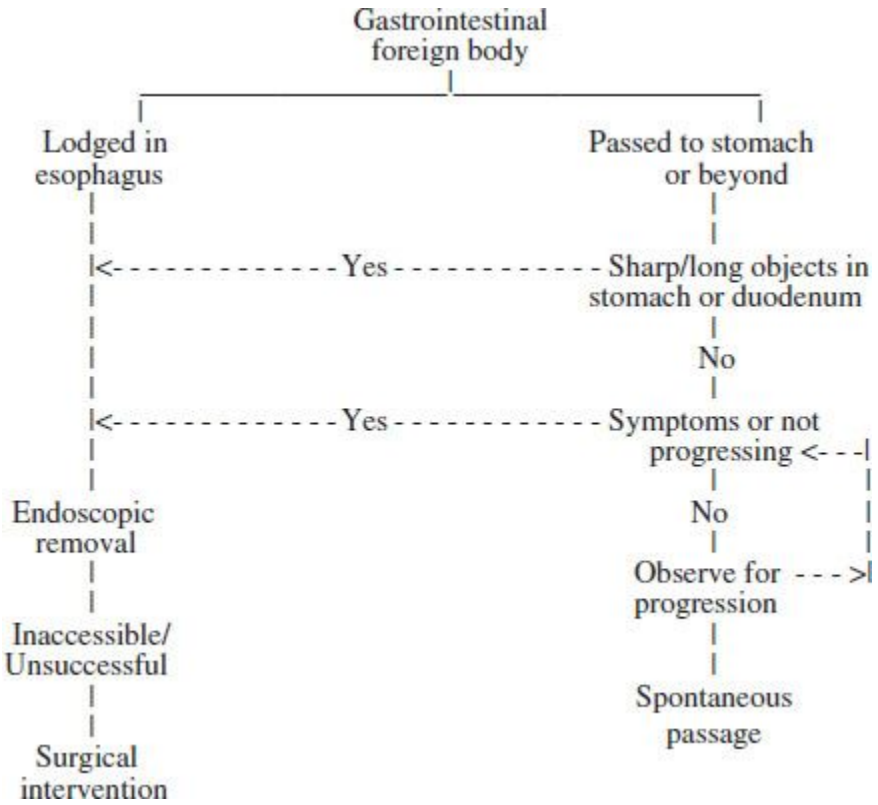

FIGURE 115.1 Management of the stable patient with a gastrointestinal foreign body.

Hypopharynx

The most common presentation is a sensation of a fish or chicken bone stuck in the throat, with distinct, well-localized pain in the throat. Well-appearing patients with negative imaging can be sent home with follow-up in 24 hours for endoscopy if still symptomatic, since most have only a mucosal abrasion. The vast majority with a mucosal abrasion will be asymptomatic at follow-up, whereas those with a true hypopharyngeal foreign body typically do not develop any complications from the delay (2). Highly symptomatic patients with severe pain and negative plain films should undergo CT, which is more sensitive for smaller bones and objects (2,8). If a bone or other impacted sharp object is identified in the hypopharynx, it should be removed promptly, typically by an otolaryngologist via nasopharyngoscopy (2).

Esophagus: Indications for Immediate Endoscopic Removal

Sharp objects in the esophagus need immediate endoscopic removal because of the risk of perforation (1). Button batteries in the esophagus are a true emergency and require immediate endoscopic removal, since serious mucosal burns and even perforation have been reported within as little as 2 hours (15). Patients with high-grade obstruction with inability to swallow secretions (usually from a meat bolus) require emergent endoscopy because of the risk of aspiration, particularly if the patient falls asleep (1,4).

All Other Blunt Esophageal Foreign Bodies

Objects in the upper half of the esophagus are unlikely to pass spontaneously, mandating intervention. The standard of care at most large institutions is prompt endoscopic removal (1,2,10,12). If the patient has a full stomach or if endoscopy is not readily

available, it may be postponed briefly as long as the patient is able to handle secretions. Most experts recommend removal within 12 to 24 hours (1,10,16).

Objects lodged at the lower esophageal sphincter are often managed with a trial of watchful waiting with or without measures to relax the sphincter, because up to 50% of these objects may pass spontaneously (16). Glucagon (1 to 2 mg IV) may be given to help relax the lower esophageal sphincter. This dose may be repeated once in 20 to 30 minutes if unsuccessful. However, its use is controversial and it may cause vomiting (2). Its efficacy has been questioned, with some authors reporting no better success than with watchful waiting (17). If passage has not occurred in 12 to 24 hours, most authors recommend endoscopic removal (1,10,16). A few small case reports and case series report success with the use of effervescent agents (such as carbonated beverages) to aid in break-up and passage of a meat bolus, but no prospective trials have validated the utility of this approach (18). Other medications such as nitroglycerin and calcium-channel blockers have been reported to be no better than glucagon (2). *Proteolytic enzymes (such as meat tenderizers) are contraindicated as they can cause severe damage to the esophageal mucosa.*

Although endoscopic removal of esophageal foreign bodies is standard at many institutions, the choice of technique is controversial in some areas because of concerns about cost or availability. A number of authors have advocated the alternative techniques of fluoroscopic Foley catheter extraction and esophageal bougienage (advancement of the foreign body with an esophageal dilator) (7,11,19). In experienced hands and in selected patients, these techniques have success and complication rates comparable to endoscopy. However, in patients with a history of prolonged impaction or a sharp-edged foreign body, the object may become embedded in the esophageal mucosa and be very difficult to remove (4). These alternative techniques should therefore be limited to patients with a blunt foreign body (usually a coin), impaction of $<$24 hours of duration, no history of esophageal disease, no

radiographic evidence of esophageal edema, and no signs of respiratory distress or airway compromise (7,9,11,19).

Advanced airway management should be immediately available at all times. The procedure should be terminated if resistance is met or multiple attempts are needed, as serious complications have occurred in these settings (11).

Cost has become less of an issue as flexible endoscopy with procedural sedation has increasingly replaced rigid endoscopy under general anesthesia in the operating room, resulting in lower charges and shorter recovery times. In many institutions, flexible endoscopy is now comparable to catheter extraction or bougienage in terms of cost and convenience.

Stomach and intestine: Objects below the diaphragm are much less problematic than those in the esophagus, because the vast majority will pass spontaneously. The exceptions are sharp objects, which may cause perforation in up to 35% of patients; these should be removed endoscopically if still in the stomach or duodenum (1,2,12). Some authors also recommend endoscopic removal of objects more than 6 cm long or 2.5 cm wide that are found in the stomach or duodenum (1), although one study of adults found that gastric foreign bodies as long as 17 cm passed into the stool without problem (3). Two special cases that usually require urgent removal by endoscopy or laparotomy are magnetic jewelry beads, which can trap bowel wall between them with resultant erosion and perforation (1,20), and objects with multiple sharp points, such that there is no blunt “leading edge” that can negotiate passage through the intestines—these are much more likely to cause perforation.

Small, blunt objects that pass into the stomach can be followed clinically, with repeat x-rays in 3 to 4 weeks if passage in the stool is not noted. A high-fiber diet may aid passage of the foreign body. Blunt objects should be given 3 to 6 weeks to pass out of the stomach before resorting to endoscopic removal (1,10). Objects may be given 2 to 3 weeks to traverse the rest of the gut. The development of symptoms or the failure of the object to progress mandates surgical consultation.

Rectum: Rectal foreign bodies frequently require surgical consultation to bring about removal, though various authors report being able to remove 20% to 75% of objects in the ED (5,6,21). Removal in the ED is dependent on the ability to achieve adequate relaxation of the anal sphincter and the ability to locate and retrieve the foreign body. Many patients with long histories of rectal stimulation will have lax anal tone and may only require lidocaine gel with or without conscious sedation to relax the sphincter. Other patients may require infiltrative local anesthesia, and some may only achieve adequate relaxation with spinal or general anesthesia in the operating room.

Soft, low-lying objects with an edge can often be grasped and removed manually or with forceps. Some objects create suction on the rectal mucosa with downward traction; this can be overcome by passing a Foley catheter beyond the object and insufflating air into the rectum (2,21,22). Sigmoidoscopy after removal is recommended to look for complications such as abscesses or mucosal lacerations, as these are very common (2,5,6,21). Hard, smooth-edged, or high-lying objects often cannot be removed manually and require surgical consultation for removal by flexible sigmoidoscopy in the operating room or endoscopy suite (6,21). Laparotomy is a last resort for foreign bodies in which sigmoidoscopy is unsuccessful.

CRITICAL INTERVENTIONS

- Immediate airway management and endoscopic intervention in patients with respiratory compromise due to an esophageal foreign body
- Immediate stabilization, antibiotics, and surgical consultation in patients with sepsis, massive GI bleeding, or perforation due to a foreign body anywhere in the GI tract
- Emergent endoscopic removal of all sharp objects, button batteries, and objects causing high-grade obstruction in the esophagus
- Prompt surgical consultation for rectal foreign bodies that are not amenable to removal in the ED

DISPOSITION

Asymptomatic patients with uncomplicated, blunt foreign bodies in the stomach or intestine can be discharged from the ED with observation of the stools or radiographic follow-up at appropriate intervals to ensure progress of the object through the gut. All others require consultation with an endoscopist or a surgeon, depending on the type and location of the foreign body and the presence of any complications. Following the uncomplicated removal of a foreign body in the ED, asymptomatic patients can be sent home with close follow-up by their primary care provider or an appropriate consultant. Patients who remain symptomatic or who develop complications after a procedure require admission.

Common Pitfalls

- Failure to consider an esophageal foreign body in patients without a foreign body history but with suggestive symptoms such as gagging, drooling, wheezing, repetitive vomiting, or refusal to eat.
- Failure to obtain immediate endoscopy for patients with high-grade esophageal obstruction, sharp esophageal foreign bodies, or button batteries in the esophagus.
- Inappropriate use of Foley catheter or other removal techniques in patients with sharp or irregularly shaped esophageal foreign bodies, prolonged impactions, esophageal edema, signs of respiratory compromise, or when initial attempts meet resistance —all of these may lead to serious complications.
- Inappropriate, repeated attempts to remove hard, smooth, or high-lying rectal foreign bodies in the ED—this may lead to further mucosal damage or even rectal perforation.
- Failure to evaluate the rectal mucosa (usually sigmoidoscopy) after removal of rectal foreign bodies to rule out mucosal lacerations.

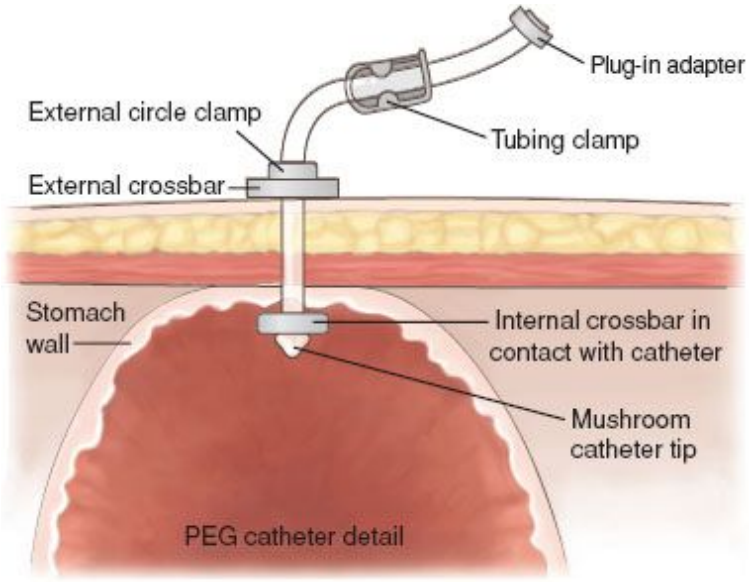
CHAPTER 116 Feeding Tubes

Philip Salen and Steven Solga

CLINICAL PRESENTATION

The assessment and management of a malfunctioning or displaced feeding tube in a debilitated, noncommunicative patient is a common clinical scenario for the ED physician. Even identifying the type of the original feeding tube, its proper placement, and the location of the ostomy may be difficult. Feeding tubes are best categorized by their site of insertion: (1) Nasal (nasogastric, nasoduodenal, and nasojejunal), (2) cervical (pharyngostomy and esophagostomy), (3) abdominal percutaneous (gastrostomy, duodenostomy, and jejunostomy) (1). For short-term enteral feeding, nasogastric tube feeding is recommended (1). Percutaneous endoscopic gastrostomy (PEG) (eFig. 116.1) is the most common device for establishing long-term enteral access in patients unable to take oral feedings because of its safety profile and low cost compared with surgically placed enterostomies (2).



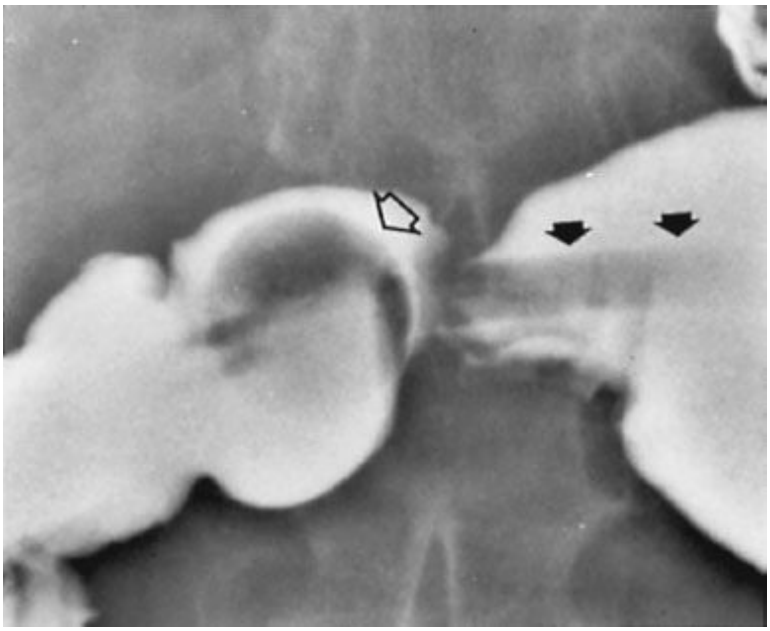
eFIGURE 116.1 Percutaneous endoscopic gastrostomy (PEG) tube in place in the stomach. Note that not all PEG devices have mushroom catheter tips nor internal crossbars; many will have balloon tips to anchor their positions. (From Smeltzer SC, Bare BG, Hinkle JH, et al. Brunner and Suddarth's Textbook of Medical Surgical Nursing. 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008:998.)

Of the many kinds of enteral feeding tubes, the PEG tube is most often encountered by the ED physician (2). There are many variants of the PEG, notably the percutaneous endoscopic jejunostomy and the percutaneous endoscopic gastrostomy/jejunostomy (PEG/J) tubes. Unlike the usual small-bore nasogastric feeding tube, PEG tubes come in different sizes ranging from 14# to 30# French. They are made of silicone, latex, or urethane, and are radio-opaque. Large-bore tubes, 20# and larger, are less likely to become occluded (3). Urinary catheters are occasionally used as PEG tube replacements, but not designed for this purpose and should only be placed temporarily in order to maintain the patency of the ostomy lumen, which can quickly shrink and close (1). PEG tubes have bumpers or balloons that aid in maintaining their positioning and come with or without external skin disks to secure their placement to the abdominal wall (see eFig. 116.1).

Jejunostomy, or J tubes, are placed surgically, endoscopically, via interventional radiology, or through the PEG. Feeding through gastrostomy tubes results in better digestion compared with intestinal feeding, whereas J tubes are less likely to result in reflux and aspiration (4). The PEG/J is a J tube that is inserted through the PEG past the pylorus with its tip in the proximal small intestine. The PEG/J allows for feeding through the J tube with less aspiration risk and for administration of medications through the PEG port with less risk of tube clogging.

ENTERAL TUBE FEEDING COMPLICATIONS

The annual incidence of enteral tube complication rate ranges from 8% to 70% (5). Enteral tube complications can be divided into mechanical, gastrointestinal, metabolic, and infectious (1). All tubes, whether nasogastric, cervical, or abdominal percutaneous, can have mechanical complications: malposition, migration, clogging, leaking, fracture, kinking, deterioration, or inadvertent removal (2). Accidental endotracheal or endobronchial nasoenteric tube insertion can result in pulmonary aspiration (1). Gastrostomy tube migration and malposition occurs when the outer bumper becomes too loose or too tight (see eFig. 116.1). Tube migration can lead to inward displacement of the internal bumper or balloon, resulting in obstruction of the pylorus with resultant vomiting, distension, or pain (see eFig. 116.2) (6). An outer bumper that is too tight can induce pressure necrosis and fasciitis, as well as a “buried bumper” where the internal bumper migrates from the stomach into the peritoneum (2).



eFIGURE 116.2 Small bowel obstruction secondary to gastrostomy tube. Feeding gastrostomy tube (open arrow) prolapsed into the duodenal bulb. The tube could be mistaken for a polyp on a large stalk (solid arrows). (From Eisenberg RL. An Atlas of Differential Diagnosis. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

A clogged PEG tube, a common ED presentation, occurs secondary to crushed medications, inadequate flushing, or precipitation of protein in the feedings administered (1). Saline flushes can crystallize within the tubing and cause obstruction. The best initial irrigant for unclogging PEG tubes is warm water (2). Clogged tubes may also be manually cleared with special "declogging" plastic brush devices, but not by wires, which can perforate the tube walls (2). The passage of water with gravity alone through the feeding tube is a good method for testing feeding tube patency (1).

Inadvertent PEG tube removal is a common complication usually occurring in combative or confused patients who pull on the tube. When PEG tubes are inadvertently removed within the first 4 weeks of placement, "blind" bedside replacement is contraindicated. The PEG tube tract may not have matured adequately resulting in gastric

and abdominal wall separation and may result in PEG placement in the peritoneal cavity or creation of a false tract (6).

Common gastrointestinal complaints associated with enteral tube feeding include nausea, abdominal cramps, and diarrhea. The diarrhea may result from drugs, antibiotics, sorbitol in the feedings, alterations in intestinal flora, fat malabsorption, contaminated feeds, and overly rapid administration of feeds (1). Enteral feed contamination by pathogenic bacteria can result in infectious diarrhea (1). Enteral feeding has the potential to cause metabolic complications, such as deficiency or excess of electrolytes, vitamins, trace elements, and hyponatremic hypervolemia as a result of excessive tube flushing with free water (2).

The ostomy site may become infected. This can be treated with oral antibiotics that cover skin flora unless the infection is severe or the patient is immunocompromised. Placement of a feeding tube does not eliminate the risk of aspiration and pneumonia. The risk of aspiration is reduced by elevating the head of the bed to 30 degrees for enteral feeding (1).

REMOVAL AND REPLACEMENT OF GASTROSTOMY TUBES

When evaluating a nonfunctioning feeding tube that is still in place, the clinician should weigh the risks and benefits of repositioning or unclogging the tube versus removing and replacing it in the ED. Other indications for PEG tube removal or replacement include progressive enlargement of the gastrostomy site, severe stomal infections, tube erosion into the gastric or abdominal wall, gastrocolocutaneous fistula, and deterioration of the tube resulting in leakage. Most tubes can be removed at the patient's bedside with gentle traction; however, the physician should investigate the timing and type of tube prior to attempting removal.

Bedside replacement of a percutaneous feeding tube carries the potential risk of inadvertent positioning into the peritoneum, with resultant peritonitis and catastrophic consequences (5). Characteristics that contribute to complications when replacing percutaneous feeding tubes include trauma to the tract during

dislodgement or replacement, tract immaturity, severe malnutrition, prolonged time interval between dislodgement and replacement, and chronic corticosteroid use.

If the tube has been removed less than 4 weeks after initial placement, the ED physician should not attempt bedside replacement. Instead, the patient should be returned to the endoscopy suite for repeat PEG placement through the same site because of the risk of site dehiscence (6). Tract site atrophy prior to replacement also mandates PEG endoscopic replacement (7). Replacement of tubes dislodged from mature fistulous tracts should be performed as soon as possible to prevent atrophy and closure of the gastrocutaneous tract. Figure 116.1 illustrates the placement of three different types of gastrostomy tubes done at the bedside. Anesthetic jelly or ointment can be placed at the stomal entrance to enhance patient comfort prior to tube placement. In most cases, tube replacement can be performed with minimal discomfort using gentle, persistent pressure of the tube through the stoma.

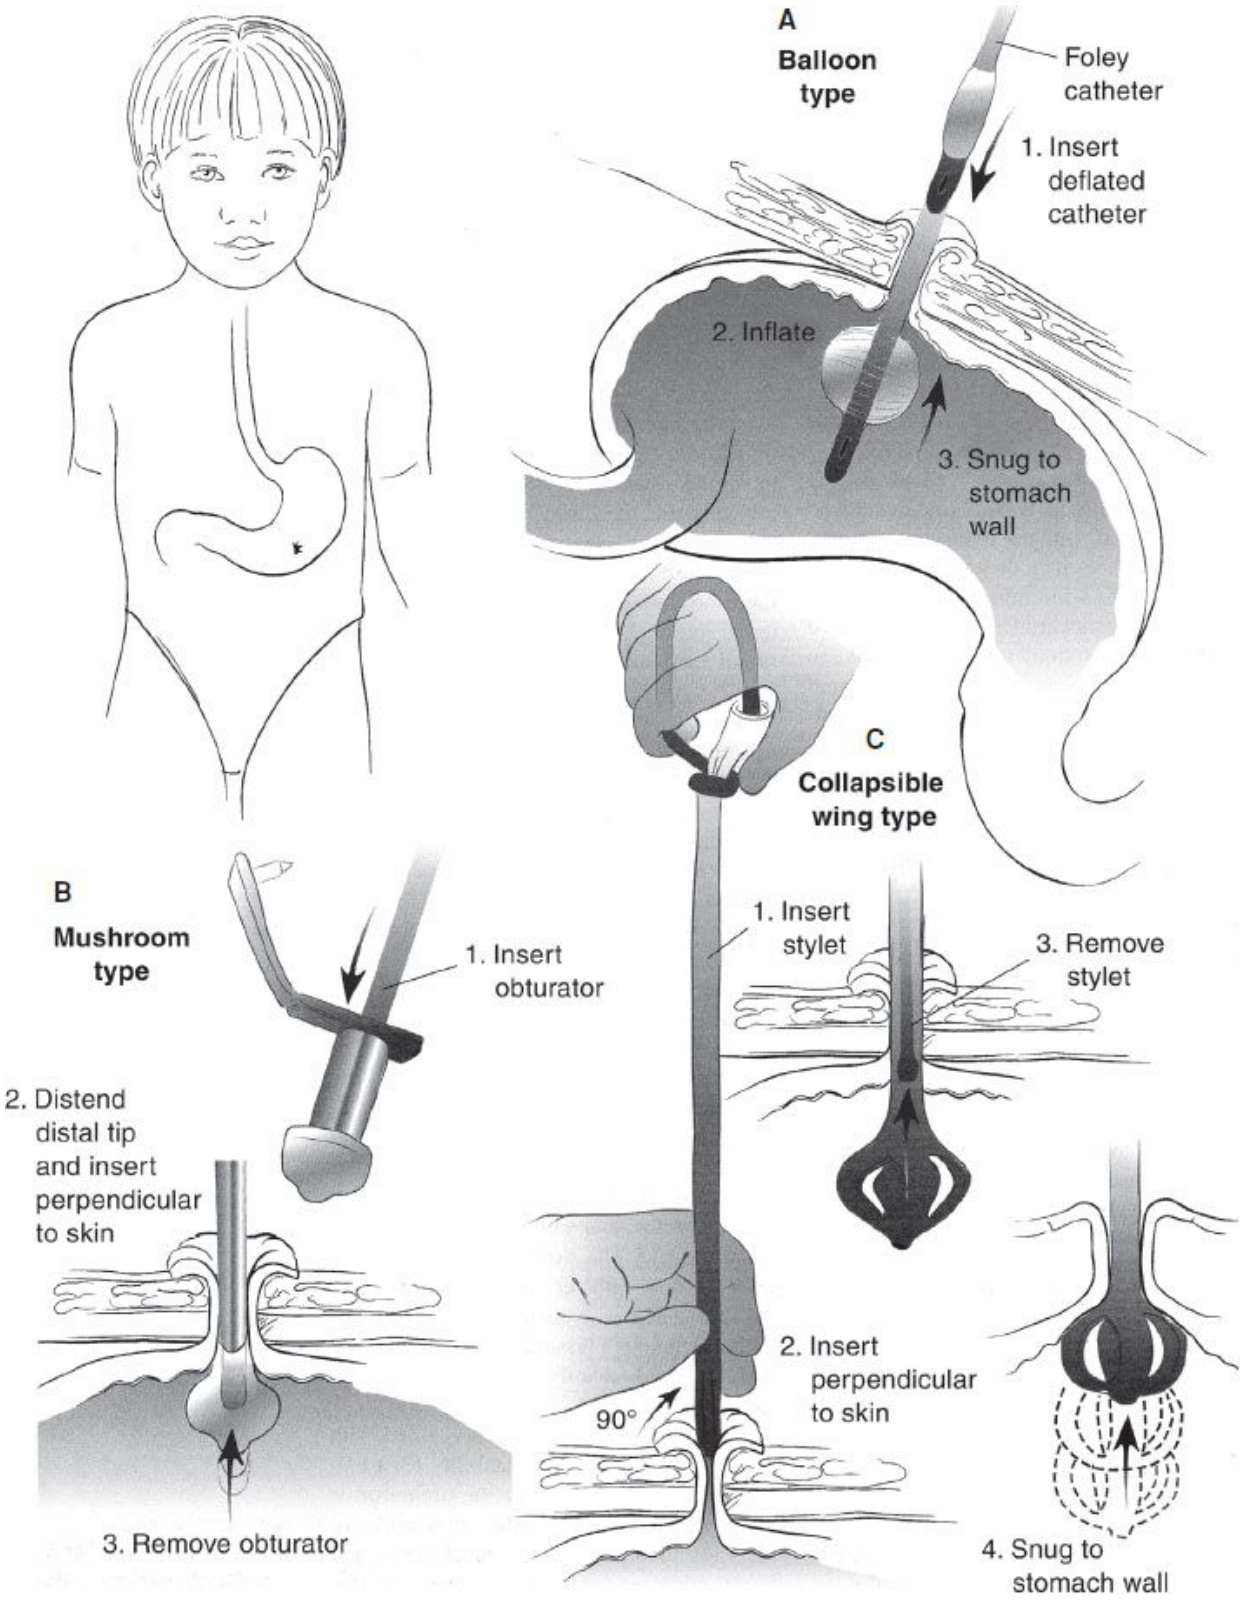


FIGURE 116.1 Three types of gastrostomy tube replacements: balloon-type **(A),** mushroom-type **(B),** and collapsible **(C)** wing-type

catheters. Note that both mushroom type and collapsible wing type catheters require stylets to distend the tip for replacement. (From Fleisher GR, Ludwig S, Henretig FM, et al. *Textbook of Pediatric Emergency Medicine.* 5th ed. Philadelphia, PA: Lippincott; 2005.)

Some advocate obtaining radiologic confirmation every time an enteric feeding tube is replaced. Others feel that radiologic confirmation is necessary only when there is a concern about tract integrity or the exact place of the tip of the feeding tube. If there is concern about the possibility of peritoneal placement of the gastrostomy tube, injecting 30 mL of water-soluble contrast solution through the gastrostomy tube followed by a supine abdominal radiograph confirms proper position prior to the initiation of feedings (6). A confirmatory contrast study is recommended following PEG replacement if the procedure is difficult, if it results in pain upon tube irrigation, or if bilious and gastric contents are not easily aspirated. The cost associated with routine radiographic confirmation pale in comparison to the cost of a single missed misplaced tube with complications (5). Other methods for confirmation of tube placement include post-insertion gastric liquid aspiration, pH testing of gastric aspirates, and auscultation for borborygmi after air insufflation into the tube (8). However, these nonradiologic methods are more liable to misinterpretation than radiologic confirmation (8). After confirmation of tube placement, the clinician must take care to adequately secure the tube, using the tube bolsters if present, to ensure that the tube is not accidentally removed and to inhibit migration. Finally, the type, size, and distance of insertion (most have markings imprinted on the side) should be recorded in the medical record, and the tube itself can be marked so that tube migration can be more easily detected (1).

CRITICAL INTERVENTIONS

- Acquire information about the enteral tube (type of tube, placement date, who placed the tube, and how it was secured) prior to removal or replacement.

- Replace a disloged PEG tube through a mature tract as soon as possible to prevent tract atrophy and closure.
- Do not attempt blind replacement of a recent tube through an immature tract (< 4 weeks).
- Confirm and document successful enteral tube replacement.

DISPOSITION

Most patients can be safely discharged from the ED after tube placement has been confirmed, and the tube may be used immediately.

Common Pitfalls

- Inadequate examination of the enteral tube ostomy site, which can suffer a myriad of complications including peristomal infection, leakage, buried bumper syndrome, and necrotizing fasciitis.
- Attempting replacement of a PEG tube into an immature gastrocutaneous tract, < 4 weeks old.
- Lack of radiographic confirmation with contrast of successful tube replacement, if the patient is at risk for complication (difficult placement, painful placement, or inability to aspirate gastric contents after placement).

SECTION XI
Renal and Urologic Emergencies

Section Editor: GREGORY W. HENDEY

CHAPTER 117

Hematuria

H. Gene Hern Jr., Abigail R. Pease, and Nicholas Gavin

Nontraumatic hematuria is surprisingly common, with an estimated prevalence in the general population ranging from 3% to 4% (1). Hematuria may be even more common in older adults; studies using home screening urinalyses in men older than 50 years reported rates of 10% to 20% (2,3). The causes of hematuria, whether it is a chief complaint or an incidental finding, range from sources as benign as vigorous exercise to potentially serious underlying disorders such as infection, renal failure, or malignancy. The challenge for the emergency physician is to differentiate between the serious and nonserious etiologies and determine the appropriate evaluation, treatment, and disposition.

CLINICAL PRESENTATION

Hematuria is generally classified into two categories: gross hematuria and microscopic hematuria. Gross hematuria refers to visibly bloody urine and often presents as a chief complaint. Microscopic hematuria is blood in the urine visible only under the microscope and is often discovered incidentally on urinalysis.

Gross hematuria can be quite distressing to patients. However, in most cases (trauma being the notable exception), there is little correlation between the amount of blood and the seriousness of the cause. Also, the color of the urine does not correlate well with the amount of blood loss; as little as 1 mL of blood in 1 L of urine is enough to discolor the urine. Substances other than blood may discolor the urine red or brown. This condition is called

pseudohematuria and may be caused by a variety of conditions such as porphyria, rhabdomyolysis, ingestion of beets or berries, or medications such as phenazopyridine or rifampin (see Table 117.1). Microscopic examination of the centrifuged urine for red blood cells (RBCs) is useful in distinguishing true hematuria from pseudohematuria. The rare discolored specimen that is heme-negative on dipstick and has no RBCs on microscopy indicates a nonheme source. A discolored specimen that is heme-positive on dipstick but without RBCs on microscopy indicates the presence of hemoglobin or myoglobin in the urine.

TABLE 117.1
Causes of Hematuria

Pseudohematuria

Pigmenturia—myoglobinuria, hemoglobinuria, porphyria

Foods—beets, blackberries, rhubarb

Drugs—phenazopyridine, rifampin

Vaginal/perineal bleeding

Hematologic

Sickle cell disease

Coagulopathy—idiopathic thrombocytopenic purpura, hemophilia

Pharmacologic anticoagulation

Glomerulonephritis—primary; poststreptococcal glomerulonephritis, IgA nephropathy, hereditary nephritis (Alport syndrome), other

—Multisystem; systemic lupus erythematosus, Goodpasture syndrome, vasculitis, other

Renal (Nonglomerular)

Pyelonephritis

Infarction

Trauma

Interstitial nephritis

Papillary necrosis

Malignancy

Vascular malformation

Postrenal

Infection—cystitis, prostatitis, urethritis

Stones/calculi

Trauma—blunt trauma, exercise, Foley catheter placement

Malignancy

Benign prostatic hypertrophy

Schistosoma haematobium

Miscellaneous

Eroding abdominal aortic aneurysm

Renal vein thrombosis

Exercise-induced hematuria

Malignant hypertension

Microscopic hematuria is defined by an abnormally high number of RBCs present in the urine on microscopy. The American Urological Association defines asymptomatic microscopic hematuria as three or more RBCs per high-powered field (HPF) on a properly

collected urine specimen (4). Although microscopy is the gold standard for diagnosis, the urine dipstick frequently replaces the time-intensive microscopic examination. Urine dipsticks accurately detect hemoglobin in very small quantities, with reported sensitivities from 91% to 100%; the specificity ranges from 65% to 99% (5,6). The high sensitivity results in more false-positive results but fewer false-negative results. A negative urine dipstick thus reliably excludes abnormal hematuria (7). A positive urine dipstick should be confirmed by microscopy to exclude hemoglobinuria or myoglobinuria.

DIFFERENTIAL DIAGNOSIS

The most common causes of nontraumatic hematuria include urinary tract infections, nephrolithiasis, glomerulonephritis, benign prostatic hypertrophy (BPH), and urologic malignancies (Table 117.1). The history and physical examination provide important clues to the underlying diagnosis.

Associated symptoms such as dysuria, urgency, and urinary frequency indicate cystitis as a likely cause. With flank pain, fever, and other systemic symptoms, pyelonephritis should be considered. Unilateral flank pain that radiates to the groin or testicle may indicate nephrolithiasis. Of note, about 15% of patients with renal calculi do not have hematuria, making it an unreliable predictor (8,9). Symptoms of BPH such as dribbling, hesitancy, and poor stream may also suggest the cause of hematuria; new vessels in the proliferating tissue may be fragile and prone to disruption. Some controversy exists as to whether there is a higher incidence of hematuria in patients with BPH than in controls (10,11). Regardless, the presence of BPH should not deter the clinician from further evaluating hematuria, because older men have a higher incidence of cancers of the genitourinary (GU) tract.

A history of a recent sore throat or skin infection should prompt consideration of poststreptococcal glomerulonephritis. Immunoglobulin A (IgA) nephropathy, often also associated with a previous upper respiratory tract infection or pharyngitis, may

present with gross hematuria as well. Concomitant hypertension and proteinuria also indicate potential glomerulonephritis. Glomerulonephritis can range in severity from mild asymptomatic hematuria to full-blown nephritic syndrome and renal failure. It is important to note that passage of clots typically excludes the presence of glomerular disease alone and should prompt further urologic evaluation for lower GU etiologies.

In asymptomatic patients, it is important to consider and assess risk factors for urologic malignancy. A number of screening studies in adults with asymptomatic hematuria show a significant risk of urinary tract malignancies, reporting rates of 3% to 5% in women and 7% to 13% in men (3,12,13). Known risk factors for malignancy include age, tobacco use, occupational exposures (e.g., aniline dyes or benzenes), pelvic irradiation, and cyclophosphamide use (5,14).

A family history of sickle cell disease, hemophilia, polycystic kidney disease, or hereditary nephritis can suggest a possible explanation of hematuria. Recent use of medications known to cause nephritis (e.g., penicillins, sulfonamides, cimetidine, and allopurinol) or anticoagulants also may be helpful in suggesting an etiology. It is important to note that hematuria in patients on anticoagulants may originate from a potentially serious lesion and should not be attributed to the anticoagulated state itself. Screening studies show similar rates of hematuria in patients on anticoagulants and in control patients, with rates of urologic cancer the same in both groups (15). A history of travel or residency in Africa or the Middle East should prompt consideration of *Schistosoma haematobium,* one of the most common causes of hematuria worldwide.

Hematuria in women that occurs during menstruation may be caused by contamination of the urine specimen during collection or by endometriosis of the urinary tract. If contamination by vaginal or perineal bleeding is suspected, obtaining a catheterized specimen after the area has been thoroughly cleaned is recommended. Urethral catheterization itself can produce small amounts of blood in the urine. Studies comparing pre- and postcatheterization

urinalyses suggest that more than three to four RBCs/HPF cannot be attributed to catheterization alone (16,17).

Finally, vigorous exercise occasionally produces hematuria (18). Whether from direct contact sports (football, boxing) or other aerobic exercise (biking, long-distance running), exercise-induced hematuria is usually short-lived and benign.

ED EVALUATION

Evaluation of hematuria begins with a urinalysis to confirm the diagnosis of true hematuria. The urinalysis is of further value in determining whether hematuria is glomerular or nonglomerular in origin. On urine microscopy, the presence of RBC casts or a multitude of dysmorphic RBCs is indicative of a glomerular source. Urinary-protein excretion >500 mg/d (on a specimen without gross blood) also indicates probable glomerular involvement. Although these signs are helpful if present, their absence does not rule out glomerular disease.

Coagulation studies should be considered in patients taking anticoagulants. A complete blood count is appropriate for the rare patient with sustained heavy bleeding or evidence of hemodynamic compromise. Electrolytes, blood urea nitrogen (BUN), and creatinine (Cr) should be ordered in patients with suspected glomerulonephritis or symptoms of renal failure. Computed tomography (CT) without contrast should be ordered to evaluate for suspected nephrolithiasis (19). CT also provides information about other potentially lethal causes of hematuria such as abdominal aortic aneurysm (20) and neoplasms of the kidney, ureter, or bladder. When CT is relatively or absolutely contraindicated, particularly in pregnant patients, ultrasound of the kidneys and bladder is the ideal first-line test to assess for nephrolithiasis.

KEY TESTING

- Urinalysis
- Blood urea nitrogen (BUN) and creatinine (if renal parenchymal disease suspected)

- Complete blood count (if significant bleeding or hemodynamic compromise are present)
- Urine culture (if symptoms of infection are present)
- CT scan of abdomen and pelvis without intravenous contrast (in patients with pain and no history of nephrolithiasis)

ED MANAGEMENT

The clinically stable patient with nontraumatic hematuria rarely requires urgent or emergent ED management (see Fig. 117.1). The rare patient with hemodynamic compromise caused by hematuria should be resuscitated with intravenous (IV) crystalloids and blood transfusion as necessary. As always, patients with significant pain and discomfort should receive appropriate analgesics.

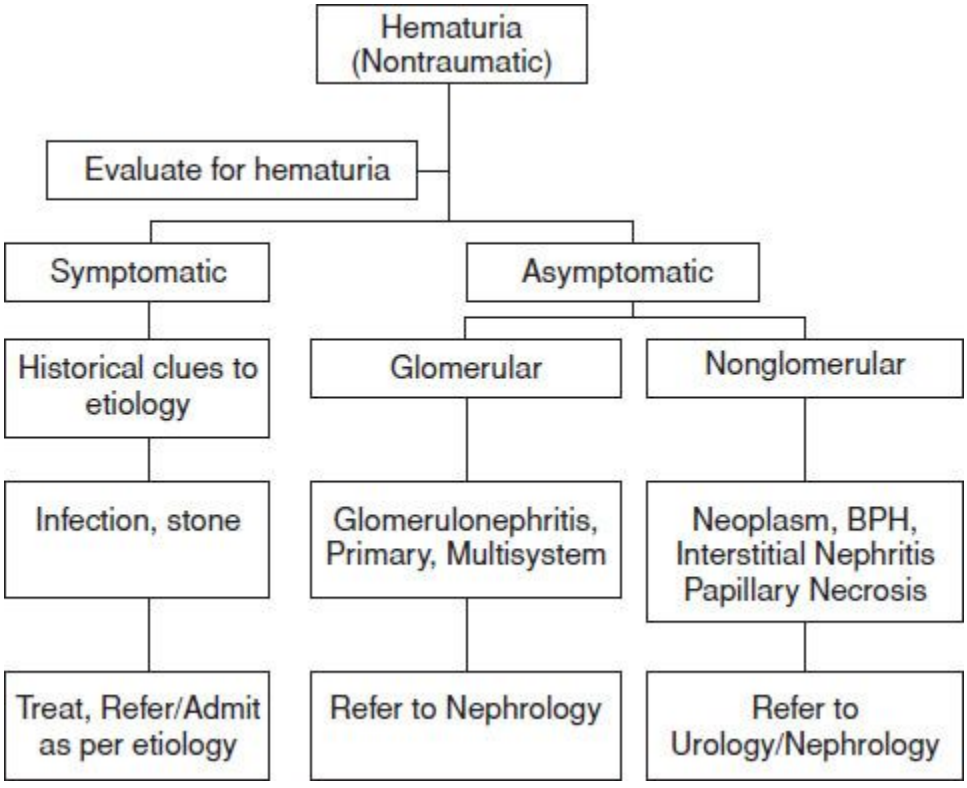

FIGURE 117.1 Approach to nontraumatic hematuria.

Further management of hematuria is directed at the cause. Urinary tract infections should be treated with appropriate antibiotics (see Chapter 123). Nephrolithiasis should be treated with

analgesics (see Chapter 126). The risk of complications associated with glomerulonephritis (e.g., volume overload, pulmonary edema, electrolyte imbalance, and oliguria) is significant, and thus consultation with a nephrologist is recommended.

With brisk bleeding, often in the postoperative setting, the formation of intravesicular clots can lead to bladder outlet obstruction. This obstruction is managed by placing a triple-lumen urinary catheter to relieve obstruction and then irrigating the bladder with normal saline until the effluent is pink or clear and free of clots.

CRITICAL INTERVENTIONS

- Volume resuscitation of any hemodynamic instability caused by severe hematuria
- Relieving obstruction and irrigating clots with a catheter as needed

DISPOSITION

Most patients with nontraumatic hematuria are managed as outpatients, regardless of cause. Patients with intractable nausea and vomiting, bladder outlet obstruction, renal failure, hemodynamic instability, or signs and symptoms of sepsis should be admitted.

Stable patients with a clear glomerular source of bleeding do not require further ED workup for a urologic source and may be referred to a nephrologist for further evaluation. Asymptomatic nonglomerular hematuria requires outpatient referral to a primary care physician, urologist, or nephrologist but not admission or emergent consultation. Patients older than 35 years, those with gross hematuria, or those with risk factors for malignancy require urgent referral to a urologist for cystoscopy and imaging of the upper urinary tract, typically CT urography. This age cut-off is lower than in past recommendations and is based on the 2012 AUA guidelines (4). Patients younger than 35 years with asymptomatic

microscopic hematuria can simply have a repeat urinalysis in 1 to 2 weeks to determine whether hematuria is persistent.

Common Pitfalls

- Failing to provide adequate follow-up for asymptomatic patients with hematuria, especially those who are older than 35 years or who have a high risk of malignancy.
- Eliminating the possibility of ureteral stone based on a negative urinalysis.

CHAPTER 118 Acute Kidney Injury

Danielle D. Campagne

The kidney functions to excrete nitrogenous metabolites (urea, creatinine, and uric acid) and to maintain volume status and electrolyte balance. Normal kidney function depends on adequate renal perfusion, efficient filtration of plasma at the glomeruli, nearly complete reabsorption of filtered solutes by the renal tubules, and the unhampered passage of formed urine from the body.

Acute kidney injury (AKI) is the new consensus term for acute renal failure. AKI, defined as a recent (within 48 hours) decline in renal function, accounts for about 1.9% of hospital admissions (1,2). In the critically ill patients who are admitted to the intensive care unit with sepsis, the prevalence of AKI is greater than 40% (2). The hallmark of AKI is azotemia, in which nitrogenous wastes such as creatinine and urea accumulate in the blood. A decrease in urine output may or may not accompany AKI. Because about 400 to 600 mOsmol of solute is created by the body every 24 hours and because maximum urine osmolality is approximately 1,200 mOsmol/L, urine output must be at least 300 to 500 mL/d to maintain adequate solute clearance from the body. *Oliguria* is thus defined as urine output $<$400 mL/d and anuria as urine output $<$100 mL/d. The term AKI implies a continuum of injury representing the entire spectrum of acute renal failure. Studies show that even small increases in serum creatinine are associated with an increased mortality (3).

AKI is staged by two commonly accepted criteria: (1) RIFLE (risk, injury, failure, loss, end-stage renal disease), and (2) AKIN (Acute Kidney Injury Network) (4). The RIFLE criteria (Table 118.1) take

into account three graded levels of renal injury (risk, injury, and failure) and two outcome measurements (loss and end-stage renal disease). The AKIN staging system (Table 118.1) differs in some important ways: (1) diagnostic criteria are applied after volume optimization, and (2) urinary obstruction needs to be excluded if oliguria was used as the sole diagnostic criterion (4).

TABLE 118.1
RIFLE and AKIN Classification of AKI

RIFLE			AKIN
Risk	Cr 1.5 × baseline (or increase 0.3 mg/dL AKIN)	UO <0.5 mL/kg/hr for 6 hrs	Stage 1
Injury	Cr 2–3 × baseline	UO <0.5 mL/kg/hr for 12 hrs	Stage 2
Failure	Cr > 3 × baseline	UO <0.3 mL/kg/h for 24 hrs or anuria for 12 hrs	Stage 3
Loss	Complete loss of kidney function >4 wks		
ESRD	Complete loss of kidney function >3 mos		

ESRD, end-stage renal disease; UO, urine output; Cr, serum creatinine; AKIN, Acute Kidney Injury Network.

Renal function is most often measured by determining the clearance of creatinine (C_{cr}), a clinical estimate of the glomerular filtration rate (GFR). Creatinine is released continuously from skeletal muscle as a by-product of the metabolism of muscle and is completely filtered at the glomerulus. Blood creatinine concentration is proportional to muscle mass and inversely proportional to GFR (5). The Cockcroft–Gault formula provides an estimate of creatinine clearance from a single measurement of serum creatinine (S_{cr}) (4):

$$C_{cr}\ (mL/min) = (140 - age)\ (lean\ body\ weight\ in\ kg)/72 \times S_{cr}\ (mg/dL)$$

The result is multiplied by 0.85 in women to correct for approximately 15% less muscle mass in proportion to body weight. These calculated results are accurate only in the steady state. For example, sudden bilateral ureteral obstruction would cause true GFR to fall to zero, but GFR calculated from the previous equation would decline only slowly, as serum creatinine increased at the rate of 1 to 3 mg/dL per day, as expected from ongoing endogenous production. Changes in GFR are eventually reflected by changes in serum creatinine, and small changes in creatinine can indicate a significantly decreased GFR.

AKI can lead to life-threatening complications such as pulmonary edema, hyperkalemia, acidemia, severe hypertension, and uremic pericarditis with effusion or tamponade. The goal of the emergency physician is to recognize and treat these complications and to halt any further decline in renal function by correcting any reversible underlying cause.

CLINICAL PRESENTATION

There are no presenting signs or symptoms that are pathognomonic for AKI. Most often, AKI occurs in the setting of other illnesses (6). Patients may present in critical condition, or asymptomatic azotemia may be discovered on routine blood screening. Some nonspecific symptoms include fatigue, weakness, shortness of breath, and peripheral edema. The diagnosis is thus established only after laboratory studies are performed. Patients rarely present because of oliguria unless it is accompanied by pain from obstruction. However, bladder outlet obstruction may be suggested by complaints of urinary frequency, incontinence, and urgency. Volume overload eventually becomes apparent in oliguric patients, but the severity of symptoms depends significantly on the patient's prior cardiovascular status.

It may be difficult to distinguish clinically between acute and recently identified chronic renal failure. A careful history, as well as laboratory evaluation, can often help (7). Patients with chronic renal failure generally have anemia, hypocalcemia,

hyperphosphatemia, and small kidneys and increased parenchymal echogenicity on ultrasound examination (8).

Uremia refers to the clinical syndrome resulting from the adverse effects of renal failure on other organ systems. These include the cardiovascular (pericarditis with or without effusion), central nervous (somnolence, coma, and seizures), gastrointestinal (nausea, vomiting, and ileus), hematologic (anemia, coagulopathy, and platelet dysfunction), and immunologic (impaired defenses and response to infection) systems (6,9). Only a minority of patients with AKI present with full-blown uremia.

DIFFERENTIAL DIAGNOSIS

AKI is classically divided into three broad etiologic categories (Table 118.2): prerenal failure (inadequate renal perfusion), intrinsic renal failure (disorders of the renal parenchyma), and postrenal failure (obstructive uropathy). Prerenal failure is the most common in both adults and children, followed by acute tubular necrosis (ATN) in adults (6) and the hemolytic uremic syndrome (HUS) in children (10). Other causes of AKI are less frequently seen.

TABLE 118.2
Common Causes of AKI

- Prerenal azotemia (decreased renal perfusion)
- Hypovolemia
  - Hemorrhage
  - Excessive diuresis
  - Vomiting or diarrhea
  - Heat losses
  - Burns
- Decreased cardiac output
  - Myocardial diseases
  - Pulmonary hypertension
  - Congestive heart failure
- Altered systemic vascular resistance
  - Sepsis
  - Cirrhosis
  - General anesthesia
- Impaired renal autoregulation
  - NSAIDs
  - Angiotensin-converting enzyme inhibitors
  - Renal arterial stenosis (atherosclerotic, fibromuscular dysplasia)
- Intrinsic renal insufficiency
- Acute tubular necrosis
  - Ischemic injury secondary to shock, hemorrhage
  - Aminoglycosides
  - Intravenous contrast agents
  - Pigment nephropathy secondary to trauma
  - Ethylene glycol
- Acute interstitial nephritis
  - Drugs (β-lactam antibiotics)
  - Infections (Legionnaire disease, hantavirus)
  - Autoimmune diseases (SLE)
  - Infiltrative process (lymphoma, sarcoidosis)
- Acute glomerulonephritis
- Vascular disease
  - Malignant hypertension
  - Vascular occlusion
- Postrenal occlusion
- Urethral obstruction
  - Prostatic hypertrophy or carcinoma
  - Cervical carcinoma
  - Urethral stricture
  - Bladder stone
- Ureteral obstruction
  - Blood clots
  - Intra-abdominal tumor
  - Bilateral calculi
  - Retroperitoneal fibrosis
  - Retroperitoneal malignancy
  - Neurogenic bladder

NSAID, nonsteroidal anti-inflammatory drug; SLE, systemic lupus erythematosus.

Prerenal failure (azotemia) is characterized by decreased renal perfusion with intact tubular function. Hypoperfusion stimulates tubular reabsorption of sodium and free water and leads to the formation of concentrated urine, with a urinary sodium often <20 mEq/L (9). Because the kidneys are essentially normal, microscopic urinalysis is usually unremarkable (6). Prerenal azotemia is seen in conditions of hypovolemia, decreased cardiac output, and altered systemic or intrarenal vascular resistance. Nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors are increasingly common causes of prerenal azotemia, especially in the elderly, who are predisposed to this condition by decreased renal function and a high incidence of coexisting disease (11). If the underlying hemodynamic disorder can be corrected, prerenal failure is, by definition, reversible.

Intrinsic renal failure may be divided into disorders affecting the glomeruli (e.g., acute glomerulonephritis), the renal interstitium (e.g., acute interstitial nephritis [AIN]), the renal vasculature (e.g., malignant hypertension), or the tubules (e.g., ATN) (6).

ATN accounts for up to 85% of intrinsic renal failure in adults (6). It is frequently self-limited and often reversible. Etiologies include ischemic insults to the kidney (e.g., shock and hemorrhage), administration of drugs (e.g., aminoglycosides and intravenous contrast agents), and pigment nephropathy (e.g., myoglobinuria occurring secondary to limb ischemia, cocaine use, hyperthermia, or crush injuries). In ATN, the tubules lose the ability to concentrate urine and to reabsorb sodium. The urine tends to have a specific gravity similar to that of serum (1.010, isosthenuria), and the urinary sodium concentration tends to be >40 mEq/L (6). On microscopic urinalysis, granular casts and tubular epithelial cells are noted in about 80% of patients (9). ATN may be either oliguric or nonoliguric, the nonoliguric variety having a better prognosis (6).

ATN due to the administration of iodinated radiocontrast agents (contrast-induced nerphropathy [CIN]) usually occurs within the first 48 hours after the contrast study and is usually reversible. Its

reported incidence varies from zero to more than 50%, depending on risk factors (11). Important risk factors include diabetes, preexisting renal insufficiency (Cr > 1.5), age older than 60, volume depletion, multiple myeloma, and higher doses of contrast (as, e.g., with percutaneous coronary intervention) (11). Renal vasoconstriction, with a consequent decrease in medullary blood flow, and direct cytotoxic effects of contrast are the presumed pathogenesis (12). Strategies to prevent this complication center around IV hydration with isotonic saline. Sodium bicarbonate (13) and N-acetylcysteine have not consistently shown benefit and their use remains controversial (2). IV fluid hydration with isotonic fluids started prior to the contrast procedure has a more favorable impact on serum creatinine at 24 hours than hydration started after the procedure (2,14).

Attempting to avoid iodinated contrast in patients with AKI, some physicians turn to magnetic resonance imaging (MRI) for imaging. However, MRI with gadolinium should not be utilized in patients with AKI or with moderate-to-severe chronic kidney disease due to the risk of nephrogenic systemic fibrosis (NSF) (4). NSF is a rare but very serious condition that involves fibrosis of skin, joints, eyes, and internal organs.

New biomarkers (urinary interleukin-18 [IL-18], neutrophil gelatinase-associated lipocalin [NGAL], and kidney injury molecule 1 [KIM-1]) show promise in helping discriminate between prerenal azotemia and ATN (15). This information can help physicians in the future determine which patients with AKI are most likely to progress to chronic kidney disease (15,16).

AIN accounts for about 10% of intrinsic renal failure in adults (6). It is usually caused by a drug hypersensitivity reaction but can also result from infection, immune-mediated disease, or other causes (17). Many drugs have been implicated in AIN, including β-lactam antibiotics, sulfonamide drugs, and NSAIDs (17). Patients with AIN may present with fever, rash, arthralgias, eosinophilia, and eosinophiluria (the latter detectable by Hansel stain of the urine). However, these findings are frequently absent, making differentiation of AIN from other causes of AKI difficult (17).

Postrenal azotemia results from obstruction of the renal collecting system at the level of the ureters, bladder, or urethra. For renal failure to develop, ureteral obstruction must be bilateral (except in patients with a single functioning kidney). Among the common causes of obstruction are prostatic hypertrophy or carcinoma, cervical carcinoma, neurogenic bladder, and urethral stricture. Ureteral obstruction may also occur as a result of blood clots, tumors, calculi, retroperitoneal fibrosis, or malignancy (18). It is important to note that patients with obstructive, postrenal failure may present with anuria, oliguria, or normal urinary output. Because the renal parenchyma is unaffected, microscopic urinalysis may reveal hematuria but is otherwise essentially normal.

ED EVALUATION

The emergency department (ED) evaluation of the patient with ARF requires a two-step approach. First, the physician should immediately determine whether life-threatening complications exist and second, attempt to determine the cause of AKI so that potentially reversible causes can be corrected.

A detailed history should be obtained, including recent exposure to new medications (especially diuretics, NSAIDs, and ACE inhibitors), intravenous contrast material, chemicals, animal venoms, unusual plants or foods, or illicit drugs (6). A history of recent hospitalization, surgery, or other intercurrent illness that might be associated with renal hypoperfusion (e.g., cirrhosis, aortic or vascular disease, or congestive heart failure) should also be sought. A history of malignancy is especially important, as these patients are at risk of AKI from obstruction, radiation nephritis, or chemotherapy. Urinary retention in conjunction with back pain or neurologic symptoms should prompt immediate evaluation for spinal cord compression. Bone pain in the elderly should suggest multiple myeloma. Recent onset of paroxysmal nocturnal dyspnea or orthopnea may suggest volume overload.

Physical examination should begin with an assessment of volume status. Hypertension, rales, peripheral edema, or jugular venous

distention suggest fluid overload. Resting tachycardia, orthostatic hypotension, dry mucous membranes, or poor skin turgor point to hypovolemia. Signs of uremia should be sought, including asterixis, alteration in mental status, and pericardial friction rub. Skin examination may reveal a generalized rash in AIN, livedo reticularis in atheroembolic renal failure, or palpable purpura with vasculitis.

After immediately life-threatening complications are ruled out, the patient should be evaluated for evidence of urinary tract obstruction. A prostate examination in men and a pelvic examination in women are mandatory. Percussion of the suprapubic area, or bedside ED ultrasonography, may reveal an enlarged bladder. Costovertebral angle tenderness may suggest ureteral obstruction. A Foley catheter should be passed after the patient attempts to void to exclude bladder outlet obstruction and to monitor urine output, even in patients without oliguria.

Laboratory analysis should include a complete blood count, electrolytes, glucose, calcium, phosphorus, blood urea nitrogen (BUN), and creatinine. The urine should be sent for microscopic analysis and determination of specific gravity, osmolality, and sodium and creatinine concentrations. Urine specific gravity, rapidly available in the ED, is a reasonable estimate of urine osmolarity, except when solutes such as glucose or radiocontrast media are present. The detection of blood on urine dipstick may actually indicate the presence of myoglobin, and a serum myoglobin or serum creatine kinase should be ordered in cases in which rhabdomyolysis is suspected. Anemia and thrombocytopenia may suggest thrombotic thrombocytopenic purpura or HUS. A pregnancy test should be done in women of childbearing age because of the unusual but important causes of AKI that are associated with pregnancy, including preeclampsia and septic abortion (2), and because radiography may be used during the evaluation. A chest radiograph aids in the determination of volume status. An electrocardiogram (ECG) should be performed to evaluate for hyperkalemia. An arterial blood gas analysis may be helpful especially if acidosis, reflected in a low serum bicarbonate, is severe.

If bladder catheterization does not reveal evidence of distal obstruction and another etiology for AKI is not readily apparent, attention must be directed at ruling out bilateral ureteral obstruction. Renal ultrasound can detect hydronephrosis with a sensitivity of 98% to 99% and a specificity of 75% to 80% (13). Despite this high sensitivity, nondilated obstructive uropathy can occur early after obstruction in cases resulting from malignancy or retroperitoneal fibrosis and in patients who are severely dehydrated (9). Noncontrast computed tomography of the renal collecting system may be helpful if ultrasonography is inconclusive or if the etiology of the obstruction is unclear (19). MRI may also be used to assess for obstruction and hydronephrosis, with the additional benefit of visualizing abnormalities of the renal arteries and veins (20).

If obstruction is not the cause of AKI, urinary electrolytes should be evaluated to determine whether renal failure is prerenal or renal (7). As previously noted, urinary sodium is frequently <20 mEq/L in prerenal azotemia (9), whereas in intrinsic renal failure, tubular reabsorption of sodium is compromised, and the urinary sodium concentration often exceeds 40 mEq/L (6). In addition, in prerenal failure, enhanced sodium and water reabsorption results in increased passive reabsorption of urea, elevating the BUN out of proportion to the serum creatinine. Hence, a BUN–creatinine ratio >20:1 suggests prerenal azotemia. The most accurate index for differentiating between prerenal and renal failure is the fractional excretion of sodium (FE_{Na}) (7), which measures the percentage of sodium presented to the renal tubules that is not reabsorbed:

$$FE_{Na} = [U_{Na}/P_{Na}]/[U_{cr}/P_{cr}]$$

In prerenal azotemia, the FE_{Na} is usually much less than 1%, whereas in intrinsic causes such as ATN or AIN it is often elevated above 3%. Urinary sodium and FE_{Na} are increased in patients who have received diuretics.

Microscopic urinalysis provides further information (6). In prerenal azotemia, the urinalysis is unremarkable; occasional hyaline casts may be all that is noted. With intrinsic renal causes of AKI, one can expect to see a more "active sediment." In ATN, the urine contains granular casts and tubular epithelial cells, individually or in casts (9). In AIN, there is often eosinophiluria and white blood cell casts. Patients with acute glomerulonephritis often have dysmorphic red blood cells and red cell casts (6). Table 118.3 lists laboratory features useful in distinguishing between prerenal azotemia and ATN.

TABLE 118.3
Distinguishing Between Prerenal Azotemia and Acute Tubular Necrosis

	Prerenal Azotemia	Acute Tubular Necrosis
BUN–creatinine ratio	>20:1	<20:1
Urinary sodium	<20 mEq/L	>40 mEq/L
Urinary osmolarity	>500	<350
Urine specific gravity	>1.020	<1.010
FE_{Na}	<1%	>2%
Urinalysis	Normal sediment or hyaline casts	Granular casts, tubular epithelial cells

BUN, blood urea nitrogen; FE_{Na}, fractional excretion of sodium.

KEY TESTING

- Urinalysis
- Electrolytes, BUN, creatinine
- Renal ultrasound is a useful initial imaging study in newly diagnosed AKI

ED MANAGEMENT

Volume overload and hyperkalemia are the most common causes of early death in AKI patients. Fluid overload is best avoided by accurate initial assessment of volume status, judicious

administration of fluids, and constant reassessment of oliguric or anuric patients. Patients who present in pulmonary edema benefit from traditional therapies (i.e., oxygen, nitrates, diuretics, and CPAP) until hemodialysis is available (21).

Hyperkalemia is a life-threatening emergency that may manifest abruptly in AKI, particularly in patients whose renal failure is caused by rhabdomyolysis. The management of hyperkalemia is discussed in Chapter 211.

Hypertension requiring immediate treatment may be managed with intravenous nitrates or sodium nitroprusside (1). The latter agent should be used for only relatively brief periods in patients with renal failure, owing to the risk of thiocyanate toxicity. Other medications with a relatively rapid onset of action include labetalol, β-blockers, α_2-agonists, and calcium-channel blockers (1).

Once potentially life-threatening complications of renal failure have been addressed, the next priority is to identify the cause of renal dysfunction and to reverse it, if possible. If the etiology appears to be postrenal, prompt relief of the obstruction can prevent further renal injury. Bladder outlet obstruction is almost always relieved by passage of a Foley catheter. Clamping the Foley catheter when large volumes of urine are released from the bladder, once a common practice, is unnecessary, even if the patient develops gross hematuria (18). If obstruction persists after bladder catheterization or if a Foley catheter cannot be placed, urologic imaging and consultation are indicated.

If the cause of renal insufficiency appears to be prerenal, intravascular volume should be replenished with intravenous crystalloid or blood. If prerenal azotemia occurs in the face of normal or increased total body sodium (e.g., congestive heart failure), efforts must be made to correct the underlying disorder to improve renal perfusion. Invasive monitoring may be necessary to monitor volume status.

The efficacy of diuretics and dopamine in oliguric patients with AKI is the subject of controversy (1,6,9,22). There are no data to support the routine use of dopamine (which can cause

tachydysrhythmias, cardiac ischemia, and digital and gut necrosis) in patients with adequate cardiac output (1,6,22). The routine use of diuretics in the initial care of AKI patients poses a number of risks. Administering a diuretic to a patient who is already volume-contracted may precipitate ischemic ATN, and administering a diuretic to a patient with obstructive uropathy might increase hydrostatic damage to the kidneys. Administering mannitol to an anuric patient can cause intravascular volume expansion and pulmonary edema. For patients with myoglobinuric renal failure, however, mannitol is recommended, in combination with volume replacement and sodium bicarbonate (23).

A number of life-threatening emergencies associated with AKI may require emergent dialysis. Nevertheless, treatments or temporizing measures are available for each and should be instituted while arrangements are made for dialysis or transfer. The indications for acute dialysis can be remembered using the mnemonic AEIOU: *a*cidosis, *e*lectrolyte abnormalities (hyperkalemia), *i*ngestions (ethylene glycol, methanol, lithium, theophylline, salicylate), volume *o*verload, and *u*remia. Central venous access with a large-bore catheter is required for hemodialysis. Should emergent dialysis be necessary, direct consultation with a nephrologist is essential to coordinate timely intervention.

CRITICAL INTERVENTIONS

- Insert a urinary catheter to both diagnose and relieve bladder outlet obstruction.
- Quickly identify and treat patients with hyperkalemia or pulmonary edema.
- Arrange emergent dialysis for those with serious complications (severe acidosis, hyperkalemia, or volume overload).

DISPOSITION

Most patients presenting to the ED with AKI should be admitted to the hospital for further evaluation and treatment. If the etiology is

clearly postrenal, consultation with urology is mandatory, as emergent surgical decompression may be indicated. For metabolic or uremic complications of renal failure, whether acute or chronic, nephrology consultation in the ED is prudent.

Nonazotemic patients with acute urinary outflow tract obstruction corrected by bladder catheterization can, in many cases, be discharged with an indwelling catheter. In these cases, urine should be cultured and close urologic follow-up arranged.

Transfer to a tertiary care facility should be considered for any patient with renal failure if dialysis is not available at the primary facility. In rare cases, the patient must be transferred to an out-of-hospital dialysis unit. In these cases, the emergency physician must ensure that the accepting physician will be immediately available upon the patient's arrival. All available and appropriate treatment modalities should be instituted before transfer, and the patient should be transported by an advanced life support unit.

Common Pitfalls

Forgetting the simple things: a prostate examination in men and a pelvic examination in women, and insertion of a Foley catheter to rule out bladder outlet obstruction.

- Failing to recognize and promptly initiate therapy for life-threatening complications, most of which can be treated before emergency dialysis is initiated. An ECG should be obtained if hyperkalemia is suspected.
- Failing to assess volume status adequately; fluid replacement may be all that is necessary to reverse prerenal azotemia.
- Delaying appropriate transfer to a center where dialysis can be performed

CHAPTER 119

Chronic Kidney Disease and Dialysis-Related Emergencies

Allan B. Wolfson

Although patients with *acute* kidney injury (AKI) have a relatively rapid loss of renal function and tend to develop clinical manifestations requiring prompt attention, patients with *chronic* renal disease have usually experienced a slow decrease in renal function over a period of months to years. They commonly present to the emergency department (ED) with subacute or chronic symptoms, often of a progressive nature, or with acute problems resulting from a superimposed illness or stress.

Standard terminology for this condition has changed over the past 10 years (1). *Chronic kidney disease* (CKD) is defined as kidney damage or decreased kidney function for 3 months or more. It is characterized by irreversible nephron loss and scarring. The term *chronic renal insufficiency,* denoting a condition in which renal function has been reduced to a moderate degree but not enough to require renal replacement therapy, has been replaced by this term (CKD) and a specification of the degree of decrease of the glomerular filtration rate (GFR) (CKD stages 1 to 5) (1). *Kidney failure,* also called *end-stage renal disease,* denotes a chronic condition in which the GFR is decreased to a low level at which clinical symptoms begin to be prominent; serious, life-threatening manifestations can be expected to develop in the absence of dialysis treatments or renal transplantation.

The causes of CKD are numerous and, as with acute renal failure, they can be classified as prerenal (vascular), intrinsic renal (glomerular and tubulointerstitial), and postrenal (obstructive) (Table 119.1). In the United States, about one-half of CKD is caused by glomerular disease, with diabetic nephropathy accounting for the largest single group. Hypertensive nephrosclerosis is another major cause, particularly among blacks. The history, physical examination, and laboratory and imaging studies may provide clues to other specific etiologies. Determining the exact etiology of CKD can allow the underlying cause to be treated and thereby slow the progression of kidney disease in some cases.

TABLE 119.1
Major Causes of Chronic Kidney Disease

Vascular	**Tubulointerstitial**
Renal arterial disease	Nephrotoxins
Hypertensive nephrosclerosis	Analgesic nephropathy
Glomerular	Hypercalcemia/nephrocalcinosis
Primary glomerulopathies	Multiple myeloma
Focal sclerosing glomerulonephritis	Sickle nephropathy
Membranoproliferative glomerulonephritis	Reflux nephropathy
Membranous glomerulonephritis	**Obstructive**
Crescentic glomerulonephritis	Nephrolithiasis
IgA nephropathy	Reflux nephropathy
Secondary glomerulopathies	Retroperitoneal fibrosis
Diabetic nephropathy	Retroperitoneal tumor
Collagen vascular disease	Prostatic obstruction
Amyloidosis	Congenital
Postinfectious	**Hereditary**
HIV nephropathy	Polycystic kidney disease
	Alport syndrome
	Medullary cystic disease

poorly defined substances appear to be responsible for many of the clinical manifestations of uremia.

Progressive loss of renal function eventually results in the syndrome of *uremia.* Uremia is associated with derangements in homeostasis and metabolism and results in specific defects in multiple organ systems (Table 119.2). Many of these manifestations are corrected or relieved by dialysis, but others are not. All tend to develop gradually in patients with CKD, although some may present acutely.

TABLE 119.2
Major Manifestations of Uremia

Derangements of Homeostasis
Sodium balance
Water balance
Hyperkalemia
Metabolic acidosis
Hypocalcemia
Hyperphosphatemia
Hypermagnesemia
Derangements of Metabolism
Azotemia
Decreased glucose tolerance
Hyperlipidemia
Specific Organ System Effects
Cardiovascular
Hypertension, volume overload, pericarditis
Pulmonary
Pulmonary edema, pleuritis
Neurologic
Lethargy, difficulty concentrating, altered mental status, seizures, myoclonic twitching, asterixis, hiccups, cramps, peripheral neuropathy
Gastrointestinal
Anorexia, nausea, vomiting, gastrointestinal ulceration, pancreatitis
Musculoskeletal
Secondary hyperparathyroidism, renal osteodystrophy, crystal-induced arthritis, myopathy, spontaneous tendon rupture, carpal tunnel syndrome
Hematologic
Anemia, altered immunity, qualitative platelet abnormality

Clinical manifestations are not always evident even when the GFR has decreased to approximately 25% of normal, especially in younger patients. Although laboratory abnormalities may be impressive, the remaining functioning nephrons may be able to compensate reasonably well. Beyond a certain point, however, significant amounts of metabolic by-products are retained. These poorly defined substances appear to be responsible for many of the clinical manifestations of uremia.

APPROACH TO THE PATIENT

Patients with untreated CKD most commonly present to the ED with nonspecific complaints such as generalized weakness, poor appetite, or increasing confusion. These are typically of insidious onset. The first clue to the diagnosis may be a laboratory finding of a reasonably well tolerated but rather severe anemia. Elevated blood urea nitrogen and serum creatinine levels can then confirm the diagnosis.

Once it has been ascertained that the patient is in no immediate danger (e.g., from life-threatening hyperkalemia), the next step is to establish the cause of renal dysfunction, determine whether it is chronic or acute, and identify any correctable cause such as volume depletion or obstruction (Table 119.3). A finding of bilaterally small kidneys on plain radiography or ultrasonography is good evidence for chronic disease, although the presence of normal-sized or large kidneys does not rule out CKD. A history of familial kidney disease, such as polycystic kidney disease or Alport syndrome, may also be helpful.

TABLE 119.3
Reversible Factors and Treatable Causes of Chronic Kidney Disease

Reversible Factors	Treatable Causes
Hypovolemia	Renal artery stenosis
Congestive heart failure	Malignant hypertension
Pericardial tamponade	Acute interstitial nephritis
Severe hypertension	Hypercalcemic nephropathy
Catabolic state/protein loads	Multiple myeloma
Nephrotoxic agents	Vasculitis (e.g., systemic lupus erythematosus, Wegener granulomatosis, periarteritis nodosa)
Obstructive disease	Obstructive nephropathy
Reflux disease	Reflux nephropathy

Laboratory abnormalities such as anemia, acidosis, hyperkalemia, hypocalcemia, and hyperphosphatemia can occur with *acute* renal failure as early as 10 days after its onset, but they tend to be better tolerated in patients with chronic renal disease. Findings on urinalysis are usually not helpful.

DIALYSIS

Patients with CKD are often sustained on chronic hemodialysis or peritoneal dialysis (PD). Nevertheless, they are subject to those complications of CKD that are not corrected by dialysis, to the manifestations of underlying systemic diseases, and to complications of the dialytic therapy itself (2–4).

There is a significant potential for iatrogenic illness owing to inappropriate fluid or drug administration. Even apparently innocuous agents, such as antacids and enemas, can cause serious problems. Physicians caring for patients with CKD should thus have ready access to a reference compendium containing guidelines for the adjustment of drug dosages in renal failure (5).

Several serious problems are commonly encountered both in dialysis patients and in those with CKD who have not yet undergone dialytic therapy, and the approach is similar in the two patient groups. The two major dialysis modalities, hemodialysis and PD, are themselves associated with specific complications with which the emergency physician should be familiar (6,7).

HEMODIALYSIS

In hemodialysis, the patient's heparinized blood passes through an extracorporeal dialyzer circuit in which it is in contact with an artificial dialysis membrane across which water and solutes from the blood diffuse. The high blood-flow rates that are necessary to make hemodialysis an efficient process necessitate special access to the patient's circulation, generally through a surgically created arteriovenous fistula or through an artificial vascular graft, both of which are usually placed in the arm, or a surgically placed tunneled catheter.

The vascular access must be treated with care to avoid causing thrombosis or bleeding or introducing infection. The blood pressure should never be taken in the involved arm, and a tourniquet should never be applied. One should avoid drawing blood from the access or placing an intravenous line in it, unless absolutely essential. Even in this case, a hemodialysis nurse should be called to access these sites whenever possible. Careful skin cleansing and sterile technique are mandatory, and firm but nonocclusive pressure should be applied to the site for 10 minutes after the puncture. The presence of a thrill both before and after the procedure should be documented.

If intravenous access is critical but otherwise impossible, an intravenous line may be placed in the access, with an automated infusion pump used to control the infusion rate.

Hemodialysis patients may present to the ED with a variety of complaints relating to the vascular access. Hemorrhage from a recent puncture site is usually easily managed with continuous, firm, but nonocclusive pressure over the site. Thrombosis, signaled by the loss of the thrill in the access, requires consultation with a vascular surgeon, who may elect to perform a radiocontrast fistulogram to infuse a thrombolytic agent, or to revise the access surgically. Forceful attempts to flush the access are inadvisable.

The most common access-related problem is access infection, which is a serious concern because of the associated risk of bacteremia and metastatic infection. Moreover, there is the risk that

the access may have to be removed because of persistent infection or poor flow.

Most access infections are staphylococcal; contamination with skin flora at the time of puncture is the most likely cause. The diagnosis of access infection is not always obvious. When there is warmth, redness, tenderness, or local induration over the area and the patient is febrile, there is little cause for confusion, but some patients lack local signs and may present with repeated episodes of bacteremia, or with fever and no obvious source of infection. In this situation, one should suspect access infection, draw blood cultures, and begin antibiotic therapy promptly.

A commonly used regimen is vancomycin 15 to 20 mg/kg given intravenously as a single loading dose. Vancomycin is minimally dialyzable and generally needs to be given only once every 4 to 7 days, making it an attractive choice for staphylococcal coverage. A third-generation cephalosporin or an aminoglycoside can be added for coverage of suspected gram-negative organism infection. Emergency physicians should be familiar with the regimens in common use in their own institutions.

Not all febrile dialysis patients need to be admitted to the hospital. After intravenous antibiotic loading, a reliable patient who otherwise feels and looks relatively well may be sent home with careful instructions to return if there is any clinical deterioration. This decision is best reached in conjunction with the consulting nephrologist.

PERITONEAL DIALYSIS

In PD, the patient's own peritoneum serves as the membrane across which diffusion of water and solutes occurs. Sterile dialysis fluid is infused into the peritoneal cavity through a surgically implanted Tenckhoff catheter. Osmotic forces generated by high concentrations of glucose in the dialysis fluid ensure adequate removal of fluid volume from the blood; this is in contrast to hemodialysis, in which the amount of fluid removed is controlled by adjusting the pressure gradient across the dialyzer membrane. PD offers several theoretical

advantages over hemodialysis: greater patient independence, smoother control of excess volume and hypertension, and avoidance of rapid solute shifts and intermittent anticoagulation.

As with hemodialysis, many of the emergency problems encountered by the patient on PD are related to access devices, in this case the peritoneal catheter. By far the most common problem is peritonitis, caused by inadvertent contamination of the peritoneal cavity when fluid exchanges are performed or by direct invasion of organisms from an infected catheter exit site. Peritonitis in these patients is as a rule less severe than other types of peritonitis. In fact, many of these infections can be treated on an outpatient basis, despite the fact that they involve the presence of a foreign body. If infection cannot be eradicated with antibiotic therapy, the catheter must be removed surgically, and the patient must be sustained on hemodialysis until placement of a new catheter once the infection has cleared.

About 60% of episodes of peritonitis are caused by gram-positive organisms, predominantly staphylococci. In most of the remainder, assorted gram-negative organisms are responsible. A small percentage is caused by fungal infection, which is usually considered an indication for catheter removal. Polymicrobial infection suggests a communication with the bowel or genitourinary tract. Approximately 15% of episodes of peritonitis are culture-negative.

The diagnosis of peritonitis is usually based on the patient's observation of cloudiness in the dialysate effluent at the time an exchange is performed. This is generally the earliest sign of peritonitis, and therefore patients are instructed to seek medical attention immediately when they notice it. Abdominal pain and fever often develop if treatment is not initiated promptly.

In the ED, the diagnosis of peritonitis is confirmed by the finding of organisms on Gram stain of the peritoneal fluid or a cell count of more than 100 white blood cells per microliter (with $>50\%$ neutrophils). This cell count corresponds approximately to the level at which cloudiness begins to be grossly detectable. The fluid is obtained using meticulous sterile technique, preferably by a dialysis

nurse when possible; a sample is also sent for culture (using blood culture bottles to increase the yield). Even in patients without cloudiness of the peritoneal effluent but who have fever, abdominal pain, or vague malaise, it is advisable to obtain a sample of fluid for examination, as the presentation of peritonitis can initially be subtle.

PD-related peritonitis can usually be treated on an outpatient basis (8,9). Treatment decisions should be made in conjunction with the patient's nephrologist or the PD nurse specialist, because these individuals are usually aware of the patient's overall medical condition, the types of infection recently experienced, and any psychosocial considerations that might affect outpatient management. Hospital admission is necessary if there is high fever, hypotension, severe abdominal pain, or nausea and vomiting or if the patient cannot continue to carry out exchanges at home.

A common empiric treatment regimen is vancomycin 15 to 30 mg/kg intraperitoneally (IP) plus ceftazidime or cefepime 1 g IP (or alternatively gentamicin) at the time of diagnosis. Further antibiotic treatment is based upon Gram stain and culture results. Additional vancomycin dosing is generally not required for 4 to 7 days, whereas the initial loading dose of ceftazidime, cefepime, or gentamicin is typically followed by a once-daily intraperitoneal maintenance dose. All antibiotics should be allowed to dwell IP for at least 6 hours. Heparin 500 to 1,000 U may be added to each bag for the first few days of treatment in an effort to decrease the risk of fibrin obstructing the catheter. Adequate analgesia should be provided as well, and arrangements should be made for the patient to be seen in 1 to 2 days to make sure the infection is responding to treatment and to check culture results and adjust therapy accordingly. Again, emergency physicians should be familiar with the regimens in common use in their own institutions.

There are several important caveats regarding the diagnosis of peritonitis. A similar clinical picture can be presented by other acute abdominal processes such as pancreatitis, diverticulitis, or ruptured viscus. To confuse the picture further, the finding of intra-abdominal free air on radiographs is often the result of its inadvertent

introduction during dialysis exchanges and does not necessarily indicate perforation (10). The finding of brownish or fecal material in the dialysate, however, mandates immediate surgical consultation.

Several other problems related to the peritoneal dialysis procedure occasionally bring the PD patient to the ED. An exit site infection or an infection of the subcutaneous catheter tunnel may present as tenderness, warmth, or induration or simply as a painless purulent exudate. Any exudate should be Gram-stained and cultured. Treatment can be started with an oral antibiotic active against skin flora, but intensive local cleansing and skin care are also a critical part of management. Closed infections of the subcutaneous tunnel may be difficult to appreciate and they respond poorly to medical therapy unless they are drained. If the patient should develop a leak of dialysis fluid from the tubing, bag, or catheter, or from around the catheter, evaluation and treatment should proceed as with peritonitis. The leaking elements must be replaced, if possible. A switch to low-volume exchanges may be helpful for leaks around the catheter, but surgical intervention may be necessary.

Difficulties with inflow or outflow of the dialysis fluid also occur occasionally. After ruling out straightforward problems such as kinked tubing or a closed clamp, the physician must consider more troublesome mechanical causes, including malposition of the catheter or obstruction of the catheter lumen; in the latter case, surgical or nephrology consultation is necessary. A common cause of poor inflow or outflow is constipation. Catheter position is usually evaluated with plain abdominal x-rays, and a contrast catheterogram may help to direct specific intervention.

CLINICAL PRESENTATION

Infection

Infections are a major cause of death in dialysis patients, and vascular access infection and peritonitis are the most common infections in hemodialysis patients and patients with PD,

respectively (6,7). Most infections are caused by the usual pathogens rather than by opportunistic organisms. The challenge for the clinician arises from the fact that classic findings may not be obvious.

Dialysis patients commonly do not present with high fever in response to infection. Rather, they are likely to have nonspecific complaints such as fatigue, malaise, decreased appetite, or generalized weakness. Some manifestations of infections may be attributed to CKD per se, to the effects of dialysis, or to other underlying medical illness. For instance, pneumonia may present as dyspnea alone, which is easily attributed to volume overload or to the effects of chronic anemia. Urinary tract infection can occur even in patients who are essentially anuric (11); upper urinary tract infection, presenting as renal colic or with symptoms typical of pyelonephritis, is most common in patients with polycystic kidney disease. These and other infections are generally treated as in any other patient, but antibiotic doses must be adjusted for CKD and the type of dialysis being used.

Hypotension

Hypotension commonly occurs in hemodialysis patients during or immediately after the dialysis procedure, but it often resolves spontaneously or responds readily to fluid infusion. It is usually the result of rapid fluid and electrolyte shifts. Patients with PD are not subject to this cause of hypotension, but they too can become volume depleted if intake does not keep up with fluid losses that occur through dialysis. Other potentially lethal causes of hypotension must also be considered; sepsis, drug effects, myocardial dysfunction, dysrhythmia, myocardial infarction, and pericardial tamponade are important considerations in patients treated by either dialysis modality. Acute electrolyte disturbances, vascular instability, anaphylactoid reaction, and air embolism are considerations primarily in hemodialysis patients.

Pericardial tamponade may develop acutely when there is bleeding into the pericardial sac or when volume depletion allows a

previously subclinical effusion to compromise cardiac filling. Tamponade in this setting generally presents with the expected physical findings, but coexisting cardiac or pulmonary disease may make the diagnosis difficult. The size of an effusion does not correlate well with the presence of tamponade. Echocardiography is useful in detecting pericardial fluid, however, and in demonstrating right ventricular collapse, which is the best indicator of tamponade. Emergency pericardiocentesis may be necessary if the patient's condition deteriorates rapidly and tamponade is thought likely; it can establish the diagnosis and buy time until definitive surgical therapy can be undertaken. Another temporizing measure, which is useful when tamponade has been precipitated by volume depletion, is intravenous saline infusion to raise filling pressures.

Dyspnea and Volume Overload

Dyspnea in the dialysis patient is most commonly caused by volume overload. In the hemodialysis patient, it usually develops during the interval between dialyses. Physical examination is not always reliable in detecting volume overload in these patients, and even chest radiographic findings may be misleading (12). The most reliable clue is a history of recent weight gain.

The definitive treatment of volume overload is dialysis, but several temporizing measures are available (Table 119.4) (13). Oxygen should be administered and the patient kept in the sitting position. Sublingual nitroglycerin can be administered quickly, does not require intravenous access, and often provides very rapid relief by reducing preload and afterload. Obviously, it should not be used if the patient is hypotensive. Intravenous nitroglycerin is an additional useful option and can be titrated to blood pressure and clinical effect.

TABLE 119.4
Treatment of Pulmonary Edema in Renal Failure

Dialysis
- Hemodialysis
- Hemofiltration
- Peritoneal dialysis

Oxygen
Nitroglycerin (sublingual or intravenous)
Intravenous opioids (but may increase the need for intubation)
Loop diuretics (if there is residual renal function)

Intravenous opioids such as hydromorphone can be given acutely, as in nondialysis patients, but may increase the need for intubation. Intravenous furosemide has a minimal diuretic effect in most dialysis patients, unless they retain significant residual renal function. Finally, the use of continuous positive airway pressure devices may make it possible to avoid intubation in some patients who would otherwise require it.

Although volume overload is the most likely cause of shortness of breath in the dialysis patient, dyspnea can also be the result of cardiac impairment of any cause, hypotension, infection, pleural or pericardial effusion, or any of the other causes of dyspnea in nondialysis patients.

Another potentially adverse effect of volume overload is severe hypertension, because blood pressure is often volume-dependent in dialysis patients. For hypertensive crisis (i.e., hypertension, usually severe, with evidence of acute end-organ dysfunction), therapy should include not only intravenous nicardipine or labetalol, but also prompt initiation or intensification of dialysis to lower blood volume.

Chest Pain

Chest pain in a dialysis patient should always suggest coronary artery disease. The leading cause of death in dialysis patients is cardiovascular disease (14,15). CKD itself appears to be a risk factor (16–19), and most patients have other risk factors such as hypertension, hyperlipidemia, and carbohydrate intolerance. Added to this are the effects of chronic anemia, intermittent or chronic

volume overload, and calcium and phosphorus disturbances. The hemodialysis procedure itself is often the occasion for additional ischemic stress to the myocardium because of transient hypoxemia and hypotension.

Initial interventions for suspected ischemic chest pain are similar to those for other patients, but particular attention should be directed toward such correctable factors as volume overload, hypertension, and anemia. The diagnosis of myocardial infarction by standard electrocardiographic (ECG) and enzyme criteria is generally not affected by the abnormalities of kidney failure (20,21). Although baseline cardiac enzyme levels may be somewhat higher than in the nondialysis population, when infarction occurs the pattern of enzyme changes is not affected. Troponin appears to be the most reliable serum marker of infarction in these patients (20–23). Decisions as to the most appropriate reperfusion therapy for dialysis patients with acute coronary syndromes should be made in concert with a cardiologist and the patient's nephrologist.

Chest pain may, of course, result from any of the other commonly incriminated causes, but in dialysis patients pericarditis should always be a consideration once myocardial ischemia has been excluded. Pericarditis (and tamponade) may occur even in well-dialyzed patients. The signs and symptoms are the same as those noted in nondialysis patients. Based on experience in undialyzed uremic patients, it has traditionally been taught that increased or intensified dialysis, without heparin anticoagulation, hastens resolution of pericarditis or prevents the development of tamponade or pericardial constriction. This remains an open question, however. For many patients with pericarditis, indomethacin can provide prompt pain relief. For others, intrapericardial instillation of corticosteroids, or pericardial stripping, is ultimately necessary.

Bleeding

Bleeding is relatively common in dialysis patients. It is at least in part related to platelet dysfunction (which is not completely corrected by dialysis) and, in hemodialysis patients, to transient

anticoagulation. It is important to ascertain the patient's usual or baseline hemoglobin level. Epoetin or darbepoetin are now administered routinely to almost all dialysis patients, but in untreated patients, the baseline hemoglobin level may be 6 to 7 g/dL. Moderately severe anemia may present with increased angina or dyspnea. Other symptoms, sometimes life-threatening ones, may be caused by occult bleeding into particular anatomic sites. Spontaneous intracranial, intraocular, pericardial, and retroperitoneal bleeding have been reported.

Treatment of acute bleeding episodes follows standard principles. Because correction of severe anemia (hematocrit $<25\%$) improves bleeding time (probably by a rheologic effect), red blood cell transfusion should be considered, and additional acute treatment with desmopressin (0.3 μg/kg intravenously or subcutaneously) or conjugated estrogens (0.6 mg/kg intravenously) should be begun. For life-threatening bleeding, cryoprecipitate infusion and platelet transfusions are recommended (6).

Neurologic Dysfunction

Neurologic dysfunction in the form of *disequilibrium syndrome* can occur during and just after the hemodialysis procedure, although usually only in patients with high blood urea nitrogen who are just initiating dialytic therapy. Typical mild manifestations are headache, nausea, and muscle cramps, whereas more severe cases may cause altered mental status and grand mal seizures. Disequilibrium is presumed to be caused by the rapid changes in intracellular composition and osmolality that occur with the removal of large volumes of fluid or the rapid correction of marked metabolic and electrolyte abnormalities. It usually resolves within a few hours after the hemodialysis treatment is completed. During dialysis, symptoms often respond promptly to intravenous infusion of mannitol or hypertonic saline. The syndrome does not occur with PD.

Because there are many other potential causes for neurologic dysfunction in these patients, however, it is unwise to attribute any

acute neurologic abnormality to the disequilibrium syndrome without carefully considering other causes, including intracranial hemorrhage, hypertensive encephalopathy, infection, and untoward drug effects. If findings are focal, appear suddenly, or fluctuate or become worse after a reasonable period of observation, attention should be directed to all of the other potential causes. Similarly, the presence of fever, papilledema, or severe hypertension should suggest more serious etiologies.

Electrolyte Abnormalities

Hyperkalemia is a common life-threatening emergency in undialyzed patients with AKI or CKD. It is also seen in dialyzed patients as a result of noncompliance with dietary restrictions or dialysis treatments or of vascular access dysfunction. On occasion, it may develop because of intercurrent disorders such as rhabdomyolysis, sepsis, or severe acidosis. Hyperkalemia is particularly dangerous because it is generally completely asymptomatic until dangerous cardiac effects develop. Although many dialysis patients chronically tolerate moderate hyperkalemia (6 to 7 mEq/L) with no apparent problem, a potassium level in this range must still be considered potentially dangerous because severe effects can develop fairly rapidly. Moreover, the ECG is occasionally completely normal even when hyperkalemia is severe, and it cannot be relied on to exclude any danger of serious hyperkalemic complications developing. Thus, the serum potassium level should always be checked.

The treatment of hyperkalemia is outlined in Chapter 211. The guidelines for treatment in dialysis patients follow those for treatment in other patients, but particular attention must be directed to avoiding volume overload, symptomatic hypocalcemia, or other potential complications of therapy. These interventions are temporizing measures only, and dialysis should be instituted (or reinstituted) as promptly as possible. A particularly convenient and effective method of decreasing the serum potassium level is by the administration of nebulized albuterol in a dose of 10 to 20 mg over

an hour, four to eight times the dose used in the typical patient with asthma. This intervention provides rapid improvement in the serum potassium concentration which is sustained for at least several hours, and appears to be associated with few side effects.

A dialysis patient in cardiac arrest should be presumed to be hyperkalemic and should receive intravenous calcium. This is one group of patients in whom this drug should still be administered routinely, as emphasized in the most recent advance cardiac life support (ACLS) guidelines.

Other electrolyte abnormalities can occur in patients with kidney failure under a variety of conditions, but the most important and the most common are hypocalcemia and hypermagnesemia. Although hypocalcemic symptoms are uncommon in dialyzed patients, they may occur in those who have not been treated with vitamin D and calcium supplementation, particularly when intravenous bicarbonate is given to treat hyperkalemia or severe acidosis. Symptomatic hypocalcemia should be treated with intravenous calcium gluconate or calcium chloride.

Mild hypermagnesemia is common in chronic kidney failure, but symptoms do not usually occur until magnesium levels are high (generally ≤ 4 mg/dL). Symptomatic hypermagnesemia is almost always a result of inadvertent ingestion of magnesium-containing antacids or laxatives. Intravenous calcium acts as a direct antagonist to the neuromuscular effects of hypermagnesemia, but is a temporizing measure. In the absence of the renal route of excretion, removal of excess magnesium from the body requires emergent dialysis.

KEY TESTING

- ECG and stat serum potassium, if suspicion for hyperkalemia
- Chest x-ray, if dyspnea and/or suspicion for volume overload
- CBC, blood chemistries including electrolytes, calcium, and magnesium
- ECG and chest x-ray as otherwise indicated
- Head CT, if suspicion for intracranial hemorrhage

- Blood cultures for suspected bacteremia or vascular access infection
- Peritoneal fluid cell count, Gram stain, and culture, if suspicion for PD-associated peritonitis

CRITICAL INTERVENTIONS

- Quickly diagnose and initiate treatment for severe complications of CKD such as hyperkalemia, fluid overload, and pericardial tamponade.
- Promptly initiate antibiotic treatment for patients with infected dialysis catheters or peritonitis.

DISPOSITION

A critical decision commonly facing the emergency physician is whether emergency dialysis is necessary for patients presenting to the ED with acute clinical problems. Some patients may have deteriorated between hemodialysis treatments or despite continuing PD. Others may have failed to undergo scheduled dialyses. The most common indication for emergency dialysis (Table 119.5) is severe volume overload or pulmonary edema; the available temporizing measures should be instituted and maintained until dialysis can be initiated. Temporizing measures may also be employed to manage malignant hypertension, severe electrolyte disturbances, or severe acidosis while awaiting the definitive treatment afforded by dialysis.

TABLE 119.5
Indications for Emergency Dialysis

Pulmonary edema
Severe uncontrollable hypertension with volume overload
Severe or uncontrolled hyperkalemia
Other severe electrolyte or acid–base disturbances
Some overdoses
Pericarditis

Uremic symptoms such as lethargy, confusion, asterixis, nausea, and vomiting indicate that dialysis is needed but are not, in and of themselves, indications for *emergency* dialysis unless they are severe. Similarly, serum creatinine and blood urea nitrogen levels correlate only roughly with uremic symptoms or life-threatening metabolic disturbances and do not by themselves indicate an urgent need for dialysis. The appearance of pericarditis, with or without pericardial tamponade, is often considered an indication for urgent or intensified dialysis, but pericarditis can occur even in well-dialyzed patients, and it is not clear that there is an increased risk of clinical deterioration if it is not treated with aggressive dialysis.

A key component of the ED management of all types of problems in the dialysis patient must always be consultation with the patient's nephrologist or dialysis nurse, both to take advantage of their expertise in caring for these patients' complicated problems and to ensure optimal continuity of care. The emergency physician nevertheless must be familiar with the evaluation and treatment of acute problems in dialysis patients so that needed emergency interventions can be initiated promptly.

Common Pitfalls

- Failing to identify treatable factors in patients who may have a reversible component of their CKD (particularly obstruction or volume depletion).
- Causing iatrogenic illness through inappropriate fluid or drug administration.
- Allowing the vascular access to be used for measuring blood pressure or drawing blood or for intravenous infusion.
- Failing to consider vascular access infection in hemodialysis patients, or peritonitis in PD patients, because of lack of specific findings on history and physical examination.
- Failing to consider the diagnosis of tamponade because the patient does not demonstrate all the classic signs and symptoms.
- Failing to treat volume overload because of a lack of specific findings.

- Overlooking anemia as a cause of increased angina or shortness of breath.
- Inappropriately attributing any neurologic dysfunction to disequilibrium syndrome.
- Failing to seek evidence of hyperkalemia by blood test or ECG.
- Inducing symptomatic hypocalcemia by ill-advised bicarbonate therapy.

CHAPTER 120 The Renal Transplant Patient

Louis G. Graff

The kidney is the most commonly transplanted organ in the United States. More than 17,000 are transplanted each year (1). Kidneys have been successfully transplanted for more than 60 years (2,3). In contrast to dialysis, transplantation allows the patient to live a normal life. Transplant patients do not need a treatment (dialysis) three times a week, do not need to restrict their diets (potassium, sodium, and fluid intake), and can have children (4,5). Therefore, transplantation is the preferred treatment for patients with end-stage renal disease.

The unique aspects of caring for the patient with a transplanted kidney must be considered when such a patient presents to the emergency department (ED). Evaluation and management of even minor problems is often complicated by the patient's immunosuppressed state and the presence of a transplant. Transplant patients often have a limited ability to tolerate illness, trauma, or other physiologic stresses. Moreover, chronic immunosuppression places them at increased risk for severe infections and often makes it difficult to evaluate emergent problems such as abdominal pain or fever. The status of the transplanted kidney must always be a concern as well. Patients may present with complications of the transplant surgery or with signs and symptoms of graft rejection.

MEDICATIONS

Treatment is often more complicated in the transplant patient because certain medications may have adverse effects or be frankly contraindicated in these patients (Table 120.1). For example, potassium-sparing diuretics can cause severe hyperkalemia in patients who are taking cyclosporine. Nephrotoxic drugs can act synergistically with cyclosporine and contribute to renal dysfunction. Lovastatin can cause a severe myopathy in patients taking cyclosporine. Also, a number of medications can increase or decrease cyclosporine, tacrolimus, and sirolimus levels (6) and thus affect drug effectiveness and toxicity (Table 120.2). Killed and antigen-based vaccines as well as immunoglobulin can be safely used in patients who have undergone transplantation. In contrast, live or attenuated vaccines are contraindicated in the immunosuppressed patient, as they can cause serious infection.

TABLE 120.1
Some Drugs to Avoid in the Renal Transplant Patient

Nephrotoxins

Gentamicin, tobramycin, vancomycin, cimetidine, ranitidine, diclofenac, amphotericin B, ketoconazole, melphalan, trimethoprim-sulfamethoxazole, azapropazone

Drugs that Decrease Cyclosporine, Tacrolimus, Sirolimus, Everolimus, or Tofacitinib Levels

Rifampin, phenobarbital, phenytoin, carbamazepine, isoniazid, nafcillin, octreotide, ticlopidine, rifabutin, valproic acid, rifapentine, St. John's wort

Drugs that Increase Cyclosporine, Tacrolimus, Sirolimus, Everolimus, or Tofacitinib Levels

Diltiazem, nifedipine, nicardipine, verapamil, danazol, bromocriptine, metoclopramide, ketoconazole, fluconazole, itraconazole, clotrimazole, erythromycin, clarithromycin, imipenem, doxycycline, methylprednisolone, oral contraceptives, allopurinol, cisapride, metoclopramide, bromocriptine, cimetidine, danazol, protease inhibitors, nephrotoxins (aminoglycosides, amphotericin B, cisplatin), troleandomycin, furanocoumarins (grapefruit)

Drugs that Inhibit Azathioprine Metabolism

Allopurinol

Potassium-Sparing Diuretics

Amiloride, spironolactone, triamterene

Lovastatin

May cause myopathy

Live or Attenuated Vaccines

Measles, mumps, rubella, oral polio, bacille Calmette–Guérin (BCG), yellow fever, and typhoid

TABLE 120.2
Adverse Effects of Renal Transplant Medications

Induction Agents

Antilymphocyte antibody (category C in pregnancy, may be excreted in milk)—fever, chills, leukopenia, dizziness

Basiliximab (category B in pregnancy, may be excreted in milk)—nausea, vomiting, headache, dizziness, bleeding, leukopenia

Daclizumab (category C in pregnancy, may be excreted in milk)—nausea, vomiting, headache, dizziness, bleeding, leukopenia

Alemtuzumab (category C in pregnancy, may be excreted in milk)—neutropenia, pancytopenia, ITP, hemolytic anemia, serious infections, fever, nausea, vomiting, headache, diarrhea, autoimmune disease

Rituximab (category C in pregnancy, excreted in milk)—serious infection, progressive multifocal leukoencephalopathy, mucocutaneous reaction, fever, headache, angioedema, glucose intolerance

Maintenance Immunosuppressive Agents

Azathioprine (category D in pregnancy, some excretion in milk)—serious infections, leukopenia, thrombocytopenia, lymphoma, skin malignancies, alopecia, nausea and vomiting, hepatotoxicity, gingival hyperplasia

Tacrolimus (category C in pregnancy, excreted in milk)—precipitation of diabetes mellitus, hypertension, lymphoma, skin malignancies, nephrotoxicity, neurotoxicity (tremor, headache, mental status change, sensory function change, insomnia), hepatotoxicity, hyperkalemia, serious infections

Cyclosporine (category C in pregnancy, excreted in milk)—serious infections, nephrotoxicity, hyperkalemia, neurotoxicity (tremor, seizure, headaches), hypertension, lymphoma, hepatotoxicity, hyperuricemia, cosmetic side effects (gingival hyperplasia, hypertrichosis)

Sirolimus (category C in pregnancy, may be excreted in milk)—anemia, leukopenia, thrombocytopenia, hypokalemia, hyperlipidemia, nephrotoxicity, hepatotoxicity

Everolimus (category D in pregnancy, may be excreted in milk)—anemia, leukopenia, thrombocytopenia, hypokalemia, hyperlipidemia, proteinuria, nephrotoxicity, hepatotoxicity, diarrhea, edema

Tofacitinib (category C in pregnancy, may be excreted in milk)—serious infection, lymphoma, nephrotoxicity, gastrointestinal perforation, headache, diarrhea, hyperlipidemia, hepatotoxicity, angioedema, arterial thrombosis (kidney, liver)

Belatacept (category C in pregnancy, excreted in milk)—serious infection, anemia, leukopenia, thrombocytopenia, hypokalemia, hyperlipidemia, proteinuria, nephrotoxicity, hepatotoxicity, diarrhea, edema, progressive multifocal leukoencephalopathy

Mycophenolate mofetil (category C in pregnancy, may be excreted in milk)—serious infections, neutropenia, gastrointestinal hemorrhage, pulmonary edema, lymphoma, hypertension

Corticosteroids—adrenal insufficiency, osteoporosis, hypertension, hyperglycemia, cataracts, avascular necrosis, peptic ulcer disease, Cushing syndrome, congestive heart failure, seizure, headaches, papilledema, glaucoma, growth suppression

Immunosuppressive induction agents such as antilymphocyte antibodies or daclizumab cause leukopenia and thrombocytopenia and may lead to infection or bleeding. Maintenance agents such as cyclosporine, tacrolimus, and azathioprine increase the patient's susceptibility to infection, particularly by opportunistic organisms. The patient's risk of cancer (especially lymphoma, cervical cancer, and skin cancer) is 3% or 4% (7). Because azathioprine causes leukopenia in >50% of patients, close monitoring of the blood count is necessary. These drugs can also cause hepatotoxicity, so liver enzymes should be checked in patients with symptoms consistent with hepatitis. In addition, liver failure can decrease the metabolism of cyclosporine and cause cyclosporine nephrotoxicity. Corticosteroids can contribute to the development of peptic ulcer disease, hypertension, accelerated coronary artery disease, diabetes, osteoporosis, aseptic necrosis of the hip, impaired healing, cataract, hemorrhagic pancreatitis, and candida pharyngitis. Newer agents such as mycophenolate mofetil and sirolimus are more costly but have lower rates of side effects than older medications (8).

In addition, the physician needs to consider whether the patient's illness might be caused by failure to take prescribed medications and the resulting complications from such noncompliance. Approximately 6% of renal transplant patients are not compliant with their medicines (9). Patients who are at higher risk for noncompliance are older, have had a longer time since transplantation, are male, and are nonwhite (9).

EARLY COMPLICATIONS OF TRANSPLANT SURGERY

Early after transplantation, postsurgical complications may cause patients to return to the ED. Acute tubular necrosis may occur if the graft preservation time before surgery was prolonged. Vascular complications such as renal artery stenosis or thrombosis or renal vein thrombosis can cause graft dysfunction or localized pain. Ureteral stenosis can cause decreased graft function as well. The cause of the patient's problem may become evident with

examination of the urinalysis, computed tomography (CT) imaging of the kidney, or evaluation of renal artery flow with Doppler ultrasound (10).

Local hematoma or lymphocele can cause pain or compromise graft function by mass effect. The immunosuppressive drugs given to prevent graft rejection also inhibit wound healing and the normal response to infection. At least 20% of patients develop a wound infection, and many others develop other infections. Most patients with surgical complications present within days or weeks of transplantation, although some complications (e.g., ureteral stenosis and smoldering infection) may have a delayed presentation.

RENAL DYSFUNCTION

Evidence of renal dysfunction should always be sought in the patient with a renal transplant, and any reversible cause of renal failure must be identified and treated promptly (Table 120.3). Small changes in the serum creatinine level may indicate important changes in renal function. For example, an increase in the serum creatinine level from 1 to 2 mg/dL represents a 50% decrease in renal function. During the first days after transplant surgery, the most common causes of renal failure are acute tubular necrosis, hyperacute rejection, urinary tract obstruction, urine leak, compression of the graft or renal artery by hematoma, and hypovolemia. During the first 12 weeks after transplant surgery, the patient may experience acute rejection, renal artery stenosis, or urinary tract obstruction. Renal failure more than 3 months after surgery is usually a result of acute rejection, chronic rejection, recurrence of underlying renal disease, or new renal disease.

TABLE 120.3
Differential Diagnosis of Renal Failure in the Renal Transplant Patient

Prerenal	Cyclosporine toxicity
Hypovolemia	Recurrence of chronic kidney disease
Renal artery stenosis	**Postrenal (Obstruction)**
Renal artery thrombosis	Prostate
Renal vein thrombosis	Abscess
Renal (Intrinsic Disease)	Urinoma
Acute rejection	Lymphocele
Chronic rejection	Ureteral stenosis at the anastomosis
Acute tubular necrosis	

All patients with renal dysfunction must be evaluated for obstruction. There are often no clues to this obstruction; the urinalysis may be normal, and urine output unchanged. Ultrasound can show hydronephrosis and confirm the diagnosis of obstruction.

Prerenal causes are often responsible for decreased renal function in transplant patients (Table 120.3). The patient may be volume-depleted or have widespread arteriosclerotic disease.

The anastomosis to the native artery may be a site of particular vulnerability to stenosis. A high blood urea nitrogen (BUN)–creatinine ratio and low urine sodium are consistent with this cause of renal failure. If the stenosis is not severe, the only sign or symptom may be severe hypertension. If the artery is completely thrombosed, the patient will have anuria. Percutaneous transluminal angioplasty with or without stent placement is the preferred approach in reversing hypertension and renal failure (11), but surgical reconstruction may be necessary. Radioisotope scanning using technetium or hippuran or Doppler ultrasound evaluation (10) can identify renal artery stenosis; complete occlusion can result in irreversible infarction unless blood flow is restored within 2 hours.

Renal vein thrombosis can also occur. Patients may present with graft pain and tenderness, fever, hypertension, hematuria, and proteinuria. The treatment is surgical intervention and/or long-term anticoagulation.

Clues to the presence of intrinsic renal disease (Table 120.3) may be found in the urinalysis. Red blood cell casts or proteinuria is seen in glomerulonephritis and vasculitis. Consideration should be given

to recurrence of the disease that originally caused renal failure, especially with systemic diseases such as diabetes mellitus or vasculitis. Glomerulonephritis may recur in the graft if the disease is still active in the original kidneys at the time of transplantation.

REJECTION

Patients with kidney transplants are always at risk for transplant rejection. Acute rejection usually occurs within 4 weeks of transplantation but can occur many months later and can result in complete loss of graft function. The precipitant is usually unknown, but the clinician should be circumspect in exposing the transplant patient to antigens, whether in the form of drugs or blood transfusions (12). The laboratory findings are often those of prerenal or intrinsic renal disease (i.e., low urine sodium level and high BUN–creatinine ratio). The kidney is enlarged and tender, and there may be fever, hypertension, or oliguria. An increased serum level of β_2-microglobulin supports the diagnosis of acute rejection, but the diagnosis is usually confirmed by percutaneous renal biopsy (11). The prognosis is poor when acute rejection occurs >6 months after transplantation or shows evidence of increased severity (by histologic grade or change in the serum creatinine) (14).

Treatment is hospitalization and administration of a combination of immunosuppressive drugs, including high-dose corticosteroids (e.g., methylprednisolone 500 to 1,000 mg/d). Chronic rejection, which cannot be treated, occurs months to years after transplantation and is manifested by a gradual deterioration of renal function.

Cyclosporine and tacrolimus are low-molecular-weight fungal metabolites that are very effective at preventing transplant rejection by depleting circulating T lymphocytes. Unfortunately, cyclosporine and tacrolimus produce nephrotoxicity (8), which usually occurs >6 weeks after transplantation. Some centers use newer agents such as belatacept to lower the risk of nephrotoxicity. In patients with drug nephrotoxicity, the BUN–creatinine ratio tends to reflect a prerenal process. The graft is not tender or swollen, and ultrasound

examination is normal. A reduction in the dose of immunosuppressives can lead to return of renal function. In practice, the question often is whether a decrease in renal function is caused by transplant rejection, thereby requiring an increase in the dose of drug, or to drug nephrotoxicity, requiring a decrease in the dose. Assays for serum drug levels can help differentiate rejection from drug nephrotoxicity.

FEVER OR INFECTION

Organ transplantation became possible because of the development of immunosuppressive agents to prevent organ rejection but at the cost of greatly increased infectious complications. An aggressive approach to identifying and treating infection has been the primary factor responsible for today's high survival rates for transplant patients.

Because the signs and symptoms of serious infection may be masked with the immunosuppression, blood cultures should be obtained for any transplant patient with fever, and hospital admission should be considered even when the source of infection cannot be identified. Uncomplicated urinary tract infections and wound infections may be treated with conventional antibiotics on an outpatient basis (15).

Renal transplant patients can develop cytomegalovirus (CMV) infection, which includes symptoms of fever, adenopathy, leukopenia, and myalgias. Complications include retinitis, pneumonitis, hepatitis, fungal and parasitic superinfection, and transplant rejection. Preoperative administration of valganciclovir, or ganciclovir and then postoperative valacyclovir, valganciclovir, or ganciclovir significantly reduces the risk of postoperative CMV infection (16). Active infection can be treated with ganciclovir or valganciclovir.

Meningitis can present very subtly in the transplant patient. Classic signs of meningitis (e.g., fever or meningismus) may not be present, and opportunistic organisms are likely to be involved. Headache is the most common symptom. The emergency physician

must have a high level of suspicion and a low threshold for performing a diagnostic lumbar puncture.

Trimethoprim-sulfamethoxazole prophylaxis has become the standard treatment in renal transplant patients because of the high risk of infections (17). *Pneumocystis carinii* pneumonia ordinarily develops in up to 12% of patients, but it is eliminated with prophylaxis. In addition, prophylaxis reduces the risk of urinary tract infection in the first 6 months from >50% to 5% (17).

ABDOMINAL PAIN

Evaluation of abdominal pain in the transplant patient is challenging because immunosuppressive medications can mask the signs and symptoms of disease. Most patients do not have fever or leukocytosis. Because of the subtle presentation and difficulty in diagnosis, delays before surgery often are substantial and correlate with increased risk of perforation and mortality (18).

The most common causes of an acute abdomen in transplant patients are similar to those in the general population: gastroduodenal bleeding or perforation, colonic bleeding or perforation, bowel obstruction, appendicitis, cholecystitis, volvulus, and ovarian torsion (18). Patients with polycystic kidney disease may have abdominal pain because of hemorrhage or infection in the cysts, if their own kidneys have not been removed. Ultrasonography can be used to evaluate these patients. Because both azathioprine and cyclosporine can cause hepatitis with abdominal pain, liver enzymes should be measured in transplant patients with abdominal pain. The transplant patient has an increased risk of developing lymphoma, probably because of chronic immunosuppression. Abdominal CT scanning can identify enlarged retroperitoneal nodes or tumor mass. Pancreatitis occurs infrequently (1%) in renal transplant patients. When pancreatitis does occur, it is often quite serious, with 80% to 100% mortality (19).

KEY TESTING

- Basic laboratory studies including BUN, creatinine, liver function tests, and urinalysis
- Renal ultrasound

CRITICAL INTERVENTIONS

- Aggressively seek the source of fever in immunosuppressed patients.
- Order an ultrasound to rule out obstruction in patients with renal dysfunction.
- Recognize and admit patients with acute rejection to the hospital.

DISPOSITION

The threshold for hospitalizing the transplant patient should be very low. One must always suspect a pathologic process, even in patients who seem to have only minor complaints. When a transplant-related problem is identified, the emergency physician should not hesitate to seek appropriate consultation or to arrange transfer of the patient to a facility with the resources to manage transplant patients. Nevertheless, the emergency physician can manage most acute problems in renal transplant patients if a thorough and meticulous approach is used.

Common Pitfalls

- Prescribing potentially nephrotoxic drugs in the renal transplant patient.
- Failing to realize that a small rise in the transplant patient's serum creatinine level may represent a relatively large decrement in renal function.
- Assuming that a normal urine output excludes obstruction as the cause of acute renal failure.
- Failing to remember that the immunosuppressed transplant patient often does not show classic signs of infection.
- Failing to remember that certain drugs may decrease cyclosporine or tacrolimus levels and lead to transplant rejection;

likewise, certain drugs may increase these drug levels and lead to toxicity.

- Failing to provide increased doses of steroids when transplant patients taking corticosteroids undergo major stress, such as surgery, myocardial infarction, major trauma, or sepsis.
- Giving a blood transfusion without a clear indication, because stimulation by exogenous antigens may lead to rejection.

CHAPTER 121 Acute Scrotal Pain

Jonathan E. Davis and Michael A. Silverman

The acute scrotum is defined as an acute painful swelling of the scrotum or its contents, accompanied by local signs or general symptoms (1). The three most common diagnoses are torsion of the testis and spermatic cord, acute epididymitis, and torsion of the appendix testis or appendix epididymis. Other causes include orchitis, acute hydrocele, varicocele, inguinal hernia, and necrotizing fasciitis of the perineum (Fournier gangrene). The ischemic insult from testicular torsion makes acute scrotal pain a true surgical emergency. The evaluation may be challenging, and time is of the essence.

Testicular torsion can occur at any age but is most common in neonates or adolescents (2). Testes predisposed to torsion lack posterior fixation to the scrotal wall and have an abnormally high attachment of a voluminous tunica vaginalis (Fig. 121.1). The tunica vaginalis normally fixes the testis and epididymis to the posterolateral surface of the scrotum (Fig. 121.2). However, complete envelopment of the testis by the tunica vaginalis permits rotation of the testis (clapper) within the tunica (bell), resulting in the classic “bell clapper” deformity. The testis and cord twist within the tunica vaginalis, thereby causing occlusion of the venous system (3). Arterial flow is decreased by both the twisting mechanism and by the edema secondary to venous occlusion. The likelihood of testicular necrosis is related to the duration of ischemia. Partial arterial flow may occur with as little as 180 degrees of rotation, and associated edema may result in complete occlusion. A median of 360 degrees of torsion—one complete rotation of the spermatic cord—has

been documented in cases of testicular salvage, with a median of 540 degrees of torsion in nonsalvageable cases (3). The variable degree of testicular ischemia makes the absolute window for testicular viability unknown. A history of continuous pain for 24 hours is usually associated with testicular loss. A salvage rate approaching 100% following manual or surgical detorsion within 6 hours of ischemic onset is often quoted (4). However, following acute detorsion, nearly half of the involved testes atrophy by more than 20% (5). An atrophic testicle may have impaired fertility, and decreased fertility of the contralateral testicle is likely.

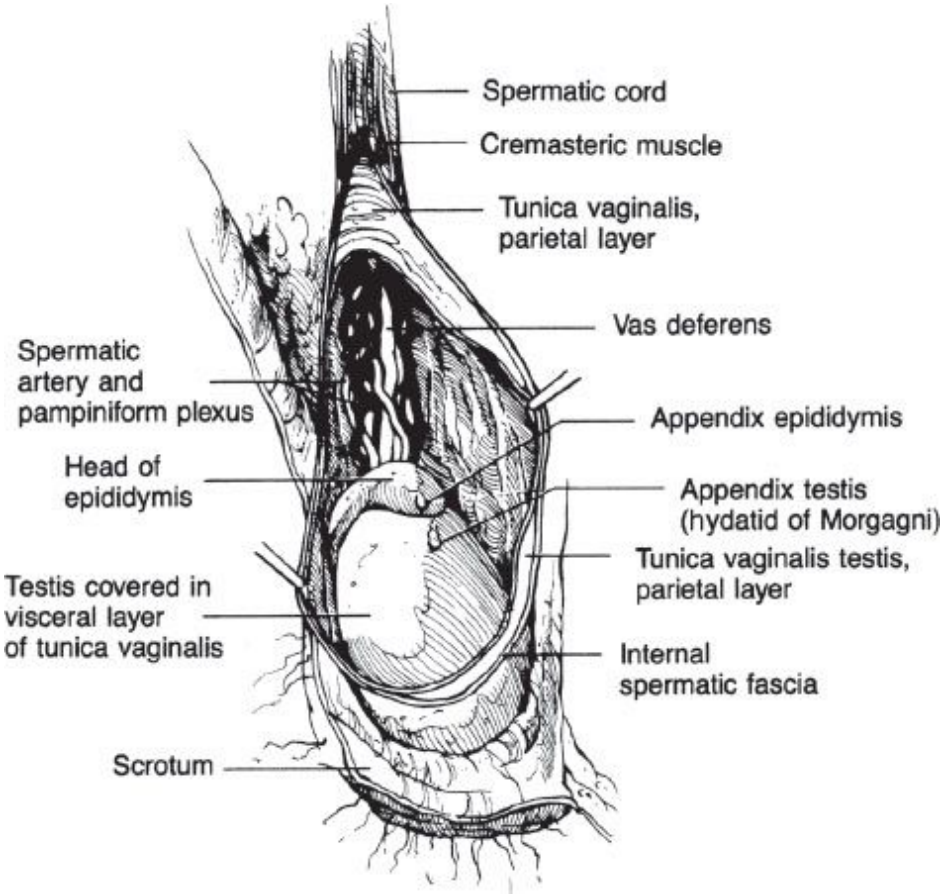

FIGURE 121.1 Bell clapper deformity.

Acute epididymitis is defined as inflammation or infection limited to the epididymis, causing acute pain and swelling of gradual onset (6). Epididymoorchitis implies extension of the inflammation or infection to the adjacent testis. Overall, epididymitis is the most common

cause of an acute scrotum (7). It is primarily a disease of adults and seldom occurs before puberty unless there is an associated anatomic abnormality that promotes urinary tract infection. Epididymitis most often results from retrograde spread of infected urine down the vas deferens into the globus minor, or tail, of the epididymis. Occasionally, reflux of sterile urine causes an inflammatory process (i.e., chemical epididymitis) (8).

In men younger than age 35, the most likely infectious agents are *Chlamydia trachomatis* and *Neisseria gonorrhoeae* (9). In men older than age 35, bacteriuria caused by obstructive urinary disease is more common, and *Escherichia coli,* enterococcus, *Pseudomonas,* and *Proteus* predominate. However, this age distinction is arbitrary. Any organism may invade the epididymis in association with a systemic infection, such as blastomycosis, tuberculosis, or meningococcus. *Candida* and *E. coli* epididymitis have been seen in patients with acquired immune deficiency syndrome (AIDS). Amiodarone (Cordarone) has been associated with drug-induced epididymitis confined to the globus major, or head, of the epididymis. In the prepubertal patient, coliform bacteria predominate. Nongonococcal bacterial epididymitis in a boy younger than age 10 should prompt a thorough diagnostic evaluation for genitourinary anomalies or neurogenic bladder disease, as underlying urogenital abnormalities exist in up to 50% of prepubertal patients with bacterial epididymitis (8,10).

Acute orchitis is an uncommon primary infection of the testis. Most often, however, orchitis is associated with a primary epididymal infection. Orchitis may occur during a systemic illness in which systemic seeding of the testis occurs with *E. coli, Klebsiella, Pseudomonas, Staphylococcus,* or *Streptococcus* species. Influenza, infectious mononucleosis, tuberculosis, syphilis, and amoebiasis may cause orchitis. The latter pathogens occur most often in immunocompromised patients. Mumps orchitis occurs in males who are systemically infected with the virus but seldom occurs before puberty. About 15% to 20% of postpubertal males with mumps develop orchitis. The onset of the testicular swelling normally occurs 3 to 7 days after the development of parotitis. One-third of men with

mumps orchitis, however, do not have parotitis. One-third of cases may be bilateral. Atrophy results in about 50% of involved testes.

Hydrocele is the most common cause of nonacute scrotal swelling. It is an accumulation of serous fluid in the potential space between the visceral and parietal layers of the tunica vaginalis that normally envelops and fixes the testis and epididymis to the posterior scrotal wall. Most hydroceles are found in older patients, and an underlying cause is not identified. A sudden onset of a symptomatic hydrocele can occur secondary to epididymitis, epididymoorchitis, trauma, or tumor. Approximately 10% of testicular tumors present with a reactive hydrocele (11). In pediatric hydroceles, congenital failure of the tunica vaginalis to be obliterated after birth allows communication between the scrotum and the peritoneum, creating a hydrocele or hernia. These "communicating hydroceles" acutely enlarge and shrink depending on patient activity, as peritoneal fluid and occasionally a loop of intestine fill the scrotum when the patient is in the upright position and spontaneously decompress when the patient is supine. This is the classic history of scrotal swelling that vanishes when the child sleeps.

CLINICAL PRESENTATION

Sudden onset of testicular pain and swelling in an adolescent is the classic presentation for testicular torsion. However, many of the other causes of an acute scrotum present in a similar manner: a male patient complaining of an acute, painful, swollen, and tender hemiscrotum. Differentiating testicular torsion from epididymitis is often challenging, particularly in cases of severe swelling and pain (eTable 121.1).

eTABLE 121.1
Differentiating Characteristics of Testicular Torsion, Epididymitis, and Appendage Torsion

	Testicular Torsion	Epididymitis	Appendage Torsion
Historical Features			
Age	Incidence peaks in neonatal and adolescent groups, but may occur at any age	Primarily adolescents and adults, but may occur at any age	Typically prepubertal males
Risk factors	Undescended testicle (neonate), rapid increase in testicular size (adolescent), failure of prior orchiopexy	Sexual activity/promiscuity, GU anomalies, GU instrumentation	Presence of appendages
Pain onset	Sudden	Gradual	Gradual or sudden
Prior episodes of similar pain	Possible (spontaneous detorsion)	Unlikely (unless prior epididymitis)	Occasional
History of trauma	Possible	Possible	Possible
Nausea/vomiting	More likely	Less likely	Less likely
Dysuria	Less likely	More likely	Less likely
Physical Findings			
Fever	Less likely	More likely, particularly in advanced disease (epididymoorchitis)	Less likely
Location of swelling/tenderness	Testicle, progressing to diffuse hemiscrotal involvement	Epididymis, progressing to diffuse hemiscrotal involvement	Localized to head of affected testicle or epididymis
Cremasteric reflex	Testicular torsion less likely if present	May be present or absent	May be present or absent
Testicle position	High-riding testicle, transverse alignment	Normal position, vertical alignment	Normal position, vertical alignment
Pyuria	Less likely	More likely	Less likely

Often, the pain is abdominal and may mimic acute gastroenteritis. In one study, scrotal pain with radiation to the abdomen or inguinal region occurred in 50% of patients with testicular torsion, whereas abdominal or inguinal pain without scrotal pain occurred in 12.5% (11). A history of a similar event can be elicited in one-half of the patients and results from previous episodes of torsion followed by spontaneous detorsion. Approximately one-half of patients report the onset of pain during sleep. Cold weather, sexual arousal, and scrotal trauma are often important inciting events. Nausea, vomiting, and low-grade fever are common clinical findings. The presence of vomiting help to heighten the suspicion for testicular torsion (12). Voiding symptoms such as dysuria, urgency, and hesitancy, although nonspecific, are typically more consistent with epididymitis.

Patients with acute epididymitis may report a gradual onset of scrotal pain and swelling that peaks over a period of 3 to 24 hours. The pain can be sharp and often radiates to the groin and either lower abdominal quadrant, simulating appendicitis or diverticulitis, but, commonly, the only complaint is a dull ache in the scrotum. Initially, the pain is felt in the tail of the epididymis. This is usually disclosed as a firm, hard mass at the inferior portion of the normally smooth testis. Over time the process extends into the body, then to the head of the epididymis, producing the large sausage-shaped mass often found on the posterior surface of the testis. A history of fever is not common in uncomplicated epididymitis, whereas patients with

more advanced degrees of infection (epididymoorchitis) may exhibit systemic signs and symptoms (13). Occasionally, a debilitated or immunocompromised patient may present with bacteremia. A history of recent cystoscopy, an indwelling urethral catheter, urinary tract infection, or genitourinary surgery should be sought, especially in older men. Similarly, a thorough history of sexually transmitted disease, exercise routines, and job-related duties should be evaluated. Activities that promote a Valsalva maneuver or increase intrapelvic pressure may promote retrograde flow of sterile or infected urine. Body builders who lift excessive weight and construction workers who climb and do heavy lifting are prototypes for the development of epididymitis. Bilateral epididymal involvement may occur infrequently. Rarely, abdominal pain attributed to infection involving the vas deferens and spermatic cord is the sole presenting symptom, and has the potential to be mistaken for appendicitis or diverticulitis.

Most hydroceles in adults develop gradually and are asymptomatic. A chronically enlarging hydrocele may present as scrotal enlargement associated with a heavy sensation, occasionally radiating to the groin. An acute hydrocele may present with pain, depending on the inciting event. The classic hydrocele is a cystic, pear-shaped mass located anterior to the testis and epididymis. It often obscures definitive palpation of the testis. A hydrocele should be confined to the scrotum, with a normal spermatic cord above it. Rarely, a hydrocele of the spermatic cord can be palpated in the region of the external inguinal canal.

DIFFERENTIAL DIAGNOSIS

In an adolescent, acute scrotal swelling is *testicular torsion* until proven otherwise. The differential diagnosis includes acute epididymitis, torsion of the testicular or epididymal appendices, orchitis, testicular tumor, inguinal hernia, and traumatic hydrocele or hematocele (eTable 121.2). Age does not preclude the diagnosis of testicular torsion. A series of 243 patients with testicular torsion revealed that 31% were prepubertal, 60% were 12 to 18 years old, 5% were older than 30 years, and isolated case reports of men into their 60s continue to be reported (14).

eTABLE 121.2
Differential Diagnosis of Scrotal Pain

Diagnosis	Symptoms	Signs	Evaluation
Appendage torsion	Typically a more indolent onset of symptoms compared with testicular torsion; less likely to present with nausea or vomiting	Tender nodule typically at head of testicle or epididymis; blue-dot sign pathognomonic	US examination may demonstrate infracted appendage
Epididymitis	Typically a more indolent onset of symptoms compared with testicular torsion; less likely to present with nausea or vomiting	*Early:* firmness and nodularity isolated to epididymis. *Late:* with progression, inflammation may become contiguous with testicle (termed epididymoorchitis)	US examination may reveal increased intratesticular blood flow, although this is a nonspecific finding
Epididymoorchitis	More likely to present with systemic findings, including nausea, vomiting, fever	Large, swollen scrotal mass typically with indistinct border between testicle and epididymis	US examination may reveal increased intratesticular blood flow, although this is a nonspecific finding
Fournier disease	Perineal pain, swelling, redness; fever, vomiting, lethargy	May present with an absence of visible local findings on skin inspection in early stages (pain out of proportion to examination); ecchymosis, crepitus, necrotic eschar may be present in more advanced disease	Emergent surgical consultation for debridement, broad-spectrum antimicrobials
Hematocele	Large, painful scrotal mass; often antecedent history of trauma	Ecchymoses of scrotal skin; testicular tenderness or firmness	US examination may reveal fluid-filled tunica vaginalis
Hernia	Unilateral inguinal or scrotal swelling and pain	Reducible, incarcerated and strangulated forms; incarcerated/strangulated hernia may be particularly tender on examination	Emergent surgical consultation when incarcerated or strangulated, outpatient surgical referral reasonable if readily reducible
Hydrocele	Typically a gradual progression of swelling	Scrotal transillumination may be helpful	US examination may reveal fluid-filled tunica vaginalis
Idiopathic scrotal edema	Typically unilateral scrotal swelling and edema; primarily seen in children less than 10 years old	Scrotal, perineal, inguinal erythema and edema; may be difficult to distinguish from an acute skin–soft tissue infection	US examination
Orchitis	Typically gradual onset of unilateral (or bilateral) testicular swelling and pain	Swelling and tenderness isolated to testis/testes without epididymal involvement	US examination; often seen in conjunction with other systemic diseases (viral, other), treatment is disease-specific
Scrotal skin infection	Variable depending on cause	Must distinguish between lesions localized to scrotal wall and those contiguous with deeper scrotal structures	US or CT imaging may be helpful in determining the depth and extent of involvement if invasive process suspected
Testicular torsion	Typically a sudden and severe onset of pain; more likely to be associated with nausea or emesis	Classic findings include an elevated testis with a transverse lie	Emergent surgery consultation in high-probability cases
Trauma	History of blunt or penetrating mechanism of injury	Variable depending on mechanism	US examination, low threshold for surgical consultation in all but the most minor injuries
Tumor	Typically a gradually progressive testicular mass, may be painless or painful in case of acute intra-tumor hemorrhage	May palpate testicular mass, firmness, or induration	US examination
Varicocele	Typically a gradual onset of unilateral swelling, often painless	Abnormally enlarged spermatic cord (pampiniform) venous plexus (often described as a "bag of worms")	US examination
Vasculitis (e.g., HSP)	Testicular swelling and pain	Associated vasculitis findings (such as buttock/lower extremity purpura and renal involvement in HSP)	US examination, other diagnostic testing guided by suspected cause (e.g., complete blood count, serum electrolytes with renal function in HSP)

CT, computed tomography; HSP, Henoch–Schonlein purpura; US, ultrasound.

Acute epididymitis, the most common entity mistaken for testicular torsion, is rare before puberty. Sixty percent of patients with epididymitis are older than 30 years. A history of urinary tract infection, painful voiding, urethral discharge, or an indwelling urethral catheter suggest the diagnosis of epididymitis. A history of previous episodes of testicular pain suggests testicular torsion. Nausea with vomiting is more common in torsion.

Primary *orchitis* seldom occurs unless it represents contiguous spread of infection from the epididymis to the testis (epididymoorchitis).

Torsion of a testicular or *epididymal appendage* can cause venous engorgement with subsequent arterial occlusion and infarction. The appendix testis is the most common appendage to twist (11). It is usually located anteriorly, near the upper pole of the testis. Appendiceal torsion occurs most frequently in the prepubertal age group (2). The onset of pain may not be as rapid as that of testicular torsion and may occur intermittently and then progress over 3 to 5 days, with less severity than testicular torsion.

Carcinoma of the testis is the most common cancer in adolescent and younger adult-aged males, a similar age range for the occurrence of testicular torsion. The initial diagnosis may be incorrect; a common misdiagnosis is epididymitis. Symptoms from testicular tumors normally have a more gradual onset, with minimal pain.

An *inguinal hernia* may present with acute scrotal swelling. An incarcerated inguinal hernia may mimic testicular torsion with an acute onset of pain, swelling, and vomiting. Most hernias may be palpated in the superior scrotal and inguinal regions (11). Uncomplicated reduction of bowel through the inguinal defect into the abdominal cavity confirms the diagnosis.

Hydrocele usually presents as a chronic, painless mass. A *hematocele* is blood or a blood clot within the potential space between the two leaves of the tunica vaginalis. It occurs most often after needle aspiration of a hydrocele, but it can accompany testicular torsion or trauma. A *varicocele* is a chronic dilatation of the testicular pampiniform venous plexus. Varicoceles are often referred to as a “bag of worms” because of the multiple torturous vessels imprinting the scrotal skin. Nearly 20% of men have a left varicocele of some degree. The left side predominates because the left testicular vein drains perpendicularly into the left renal vein without valves to reduce hydrostatic pressure, as compared with the right testicular vein, which drains obliquely into the inferior vena cava.

ED EVALUATION

A rapid presumptive diagnosis of testicular torsion should be suspected on the basis of the history and physical examination findings. Because the acute scrotum has many possible causes, testicular torsion must be the primary consideration for any scrotal complaint in any age group, but particularly in young and adolescent males.

Physical examination of the male external genitalia should be done systematically in both the supine and standing positions. After assessing the penis and foreskin, both testes are compared for size and consistency. The testes normally are oriented vertically with a slight and forward tilt. The rubbery consistency should be homogeneous and the surface is smooth. The testes should be freely mobile within the scrotum (Fig. 121.2).

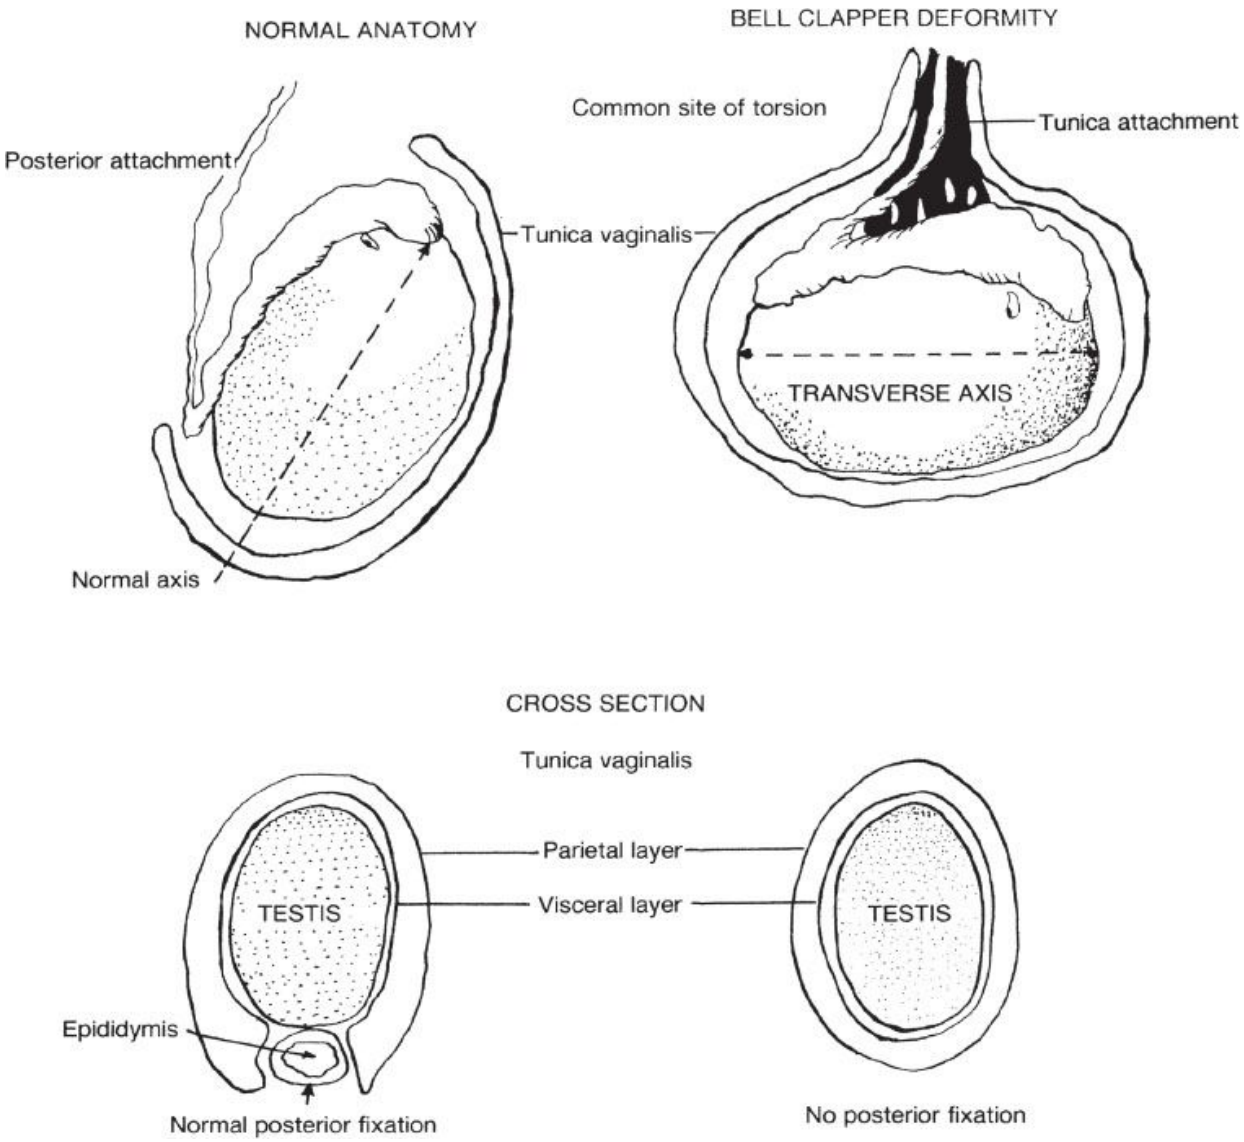

FIGURE 121.2 Normal anatomy of the scrotum.

The epididymis is a 1-cm thick, discrete, sausage-shaped structure, usually located on and firmly attached to the posterior wall of the testicle. Rarely, it is anteriorly oriented. The epididymal head is the thickest portion and lies on the top of the testis. The body of the epididymis is a continuation of the head and tapers to the tail, which is contiguous with the vas deferens. The 1- × 3-mm testicular and epididymal appendages are not normally palpable but are most commonly located anteriorly, near the upper pole of the testis and the head of the epididymis.

From the testis, the spermatic cord can be palpated ascending into the fascial cleft of the subcutaneous external inguinal ring. The vas deferens is a firm tubular structure lying within the cord. The spermatic arteries are not palpable, and the veins are palpable only when enlarged (varicocele). With the patient in a standing position, a cough or Valsalva maneuver may elicit a hernia, or may accentuate a varicocele.

The patient with testicular torsion may have a painful or nonpalpable testis that has elevated in the hemiscrotum due to the twisting and shortening of the spermatic cord. Engorgement of the testicle and secondary swelling of the scrotum are usually present. Instead of lying in the usual vertical orientation, the affected testis is often found lying horizontally in the scrotum because of its abnormal mobility within the tunica vaginalis. The spermatic cord tends to become thickened in the area of torsion.

In epididymititis, a localized, indurated, tender portion of the epididymis may be palpated inferiorly and separate from a less painful testis. Eventually, the entire epididymis becomes involved, and the distinction between the testis and epididymis is less evident (epididymoorchitis). The involved testis hangs low in an erythematous and edematous scrotum. Often the entire hemiscrotum is swollen, tender, and firm. The overlying scrotal skin rapidly develops redness and edema, and within a few hours, the testis and epididymis are no longer anatomically separable. In a series of 206 patients with torsion, 42% presented with swelling and precluded palpation of the intrascrotal contents (15).

The presence of an intact ipsilateral cremasteric reflex may be helpful in placing testicular torsion lower in the differential diagnosis, but a preserved reflex certainly does *not* exclude the diagnosis of testicular torsion (16,17). The cremasteric reflex is a superficial skin reflex mediated by spinal nerves T-12 to L-2, elicited by stroking the skin of the inner aspect of the ipsilateral thigh in an upward motion, resulting in contraction of the cremasteric muscle and elevation of the testis by at least 0.5 cm. This is best demonstrated with the patient in the supine, frogleg position and requires the absence of any inflammatory process in the overlying

scrotal skin. Certain individuals may lack the reflex altogether, particularly boys in the first 3 years of life (18).

The often-referenced “blue-dot” sign is pathognomonic for appendage torsion and refers to a small, tender, infarcted (blue), pea-like structure seen through the hormonally unstimulated thin and transparent prepubertal scrotal skin held taut over the head of the testis. This finding is very specific, yet insensitive (19).

Laboratory data are nonspecific and often not helpful. One-third of patients with torsion have a nonspecific leukocytosis of more than 10,000 white blood cells per cubic millimeter, and most patients have a normal urinalysis (11,15). A properly collected urinalysis shows pyuria or bacteriuria in 50% of patients with epididymitis, and a small number of patients have a urethral discharge that can be Gram-stained (20).

Diagnostic imaging tests such as color Doppler ultrasound or radionuclide testicular scintigraphy are always adjunctive and should never delay urologic consultation, attempted manual detorsion, or scrotal exploration. These adjunctive tests are not required to make the diagnosis. *Color Doppler ultrasound* yields the most information in the evaluation of the acute scrotum because it provides information about both anatomy and arterial perfusion. It is helpful, yet imperfect, in excluding testicular torsion (21). Color Doppler ultrasound evaluates for intratesticular blood flow. Gray-scale ultrasound is also helpful in evaluating the spermatic cord itself for twists or kinks consistent with cord torsion (22). Ultrasound evaluation can also determine whether a mass is intratesticular or extratesticular and is particularly applicable when swelling or a reactive hydrocele has made physical examination difficult or impossible. The normal testis has characteristic echoes that are homogeneous and finely granular, whereas the epididymis is distinguished by its coarser texture. A typical testicular tumor is detected as a hypoechoic, inhomogeneous mass within the testis. Epididymitis displays a thickened and enlarged epididymis. Abscess cavities may be apparent within both the testes and epididymis.

Although ultrasound studies are helpful, an aggregate clinical impression derived from a thorough history and physical

examination is more important. The imaging test used often depends on the consultant, the availability of the examination, the quality of the equipment, and the experience of the technician and radiologist reader. Adjunctive tests should never delay operative exploration. Imaging may be obtained while waiting for an operating suite, but it is imperative that the examining clinician remember that testicular torsion is definitively diagnosed at surgical exploration. Once the diagnosis of testicular torsion is suspected, immediate surgical consultation is initiated. Meticulous charting and documentation of the history and physical examination, the suspected diagnosis, and need for scrotal exploration, as well as the time course for all of these events, are imperative (23).

If the surgeon requests adjunctive testing, this must be documented in the ED record. The urologist should be informed that an attempt at manual detorsion will be made while awaiting the patient's transfer to the operating room or the radiology suite. If the urologist discourages or requests that detorsion not be attempted, this should be documented.

KEY TESTING

- Color Doppler Ultrasound in equivocal cases (must not delay surgical intervention)

ED MANAGEMENT

In patients with *testicular torsion,* manual detorsion is successful in 30% to 70% of patients (24,25). Spontaneous or successful manipulative preoperative testicular detorsion results in a high testicular salvage rate if accomplished quickly. Manual detorsion can be attempted with the patient standing or supine but most often is done with the patient supine, in bed, or on a stretcher, with the physician standing on the patient's right side. Classically, the patient is placed in the frogleg lithotomy position. Light sedation or spermatic cord block may be done to lessen the patient's discomfort. A spermatic cord block allows multiple detorsion attempts and experimentation with direction, but it eliminates pain relief as an

end point to judge successful detorsion. Documentation of return of intratesticular blood flow on color Doppler ultrasound imaging can be utilized as an alternative. About two-thirds of testes twist in a lateral-to-medial direction, so manual detorsion is initially attempted from medial to lateral, similar to opening a book; that is, the patient's right testis is detorsed in a counterclockwise direction, and the left testis in a clockwise direction (3). The testis is rotated 180 degrees in one direction and maintained in position. Further rotation is continued as necessary. If the initial detorsion increases the pain, the detorsion should be attempted in the opposite direction. Operating room data show that torsion may vary from 180 to 1,080 degrees, so continued detorsion should be guided by the patient's response (3). One to three turns are usually sufficient. The detorsion is stopped when either the anatomy is restored or the testicular pain is relieved. Both should occur promptly. Significant swelling makes the initial detorsion maneuver more difficult and there is much less chance of success. Manual detorsion should be followed by surgical exploration to confirm success and fixate both testes (orchiopexy), because torsion is an anatomic abnormality and tends to be bilateral.

The technique of spermatic cord block is straightforward. The spermatic cord is palpated and encircled with the nondominant hand at the scrotal inguinal junction. Three to four injections with 1% plain lidocaine are made at different angled approaches with a 25-gauge, 1.5-in needle. An alternative method can be instituted if the cord cannot be palpated because of severe pain or pronounced swelling. After palpating the pubic tubercle, a needle is inserted vertically downward, 1 cm below and medial to the pubic tubercle onto the anterior aspect of the pubic bone. Repeated slow injections should be made at different angles, attempting to infiltrate the area around the ilioinguinal nerve and genital branch of the genitofemoral nerve. The duration of a successful lidocaine spermatic cord block is about 1 to 3 hours.

Aggressive initial management of *acute epididymitis* is crucial to reduce the potential morbidity associated with this disease process. Bedrest, scrotal elevation with ice applied to the affected epididymis for 10 minutes three times per day, organism-specific antibiotic

therapy, nonsteroidal anti-inflammatory drugs, narcotic pain medication, and stool softeners are the initial treatment modalities recommended for acute epididymitis. Once pain-free in bed, patients may be ambulatory with a scrotal supporter and instructed not to lift or strain, as this may exacerbate the inflammatory process.

Antibiotics should be prescribed in all cases of epididymitis. Despite an infectious cause, cultures of the urine and urethral discharge may be negative. In younger patients with suspected sexually transmitted disease, a single 250-mg intramuscular dose of ceftriaxone should be administered in the ED, along with a 10-day course of doxycycline 100 mg orally every 12 hours. Because of high rates of resistance, both quinolones and oral cephalosporins are no longer recommended (26). Older men suspected of having a urinary source of infection caused by enteric gram-negative bacilli or *Pseudomonas* should be initially treated with ofloxacin 300 mg orally every 12 hours for 10 days, or levofloxacin 500 mg orally daily for 10 days. Urology follow-up is encouraged within 5 to 7 days.

CRITICAL INTERVENTIONS

- Consult a surgeon (urologist, pediatric surgeon, or general surgeon) immediately for a highly suspicious case of testicular torsion, without adding the delay of diagnostic studies.
- Perform manual detorsion while the patient awaits the operating room, in order to reduce the ischemic time to the testicle.
- Provide antibiotics and analgesics for patients with acute epididymitis.
- Neither the presence of an intact cremasteric reflex nor intratesticular blood flow on color Doppler ultrasound precludes the diagnosis of testicular torsion—if suspicion is high, specialty consultation is necessary.

DISPOSITION

The surgeon is obligated to establish a final diagnosis and perform definitive *orchiopexy* or *orchiectomy,* depending on the operative findings. Selected ancillary tests must not delay surgical exploration.

When securing written informed operative consent, the consultant should explain the need for bilateral orchiopexy, the possibility of orchiectomy, and the option for placement of a testicular prosthesis. An unequivocally infarcted testis is usually removed at exploration to lessen the chance for persistent pain and promote resolution of the inflammatory process. Bilateral orchiopexy is indicated, because the anatomic defect is present bilaterally.

All patients for whom testicular torsion is strongly suspected should be explored in the operating suite. Observation and serial examinations are not useful in the management of suspected testicular torsion. If preoperative manual detorsion successfully re-establishes testicular blood flow, arrangements for delayed orchiopexy can be made by the consultant, who is ultimately responsible for any planned delay in scrotal exploration and orchiopexy. The unavailability of a qualified surgeon, or immediate operating room facilities, warrants consideration of prompt transfer.

Outpatient management of epididymitis is appropriate in most cases. Urologic follow-up should be arranged for 5 to 7 days, unless worsening of the patient's condition necessitates an earlier visit. Pediatric cases of epididymitis require urologic consultation to evaluate the potential for lower urinary tract anomalies and urinary obstruction as the cause of the epididymitis. Adult patients with suspected bacteremia or severe constitutional symptoms, including intractable pain or nausea and vomiting, require hospitalization and parenteral antibiotics. Patients in whom the physical examination and ultrasonography are equivocal for abscess formation should also be admitted for antibiotic therapy and further evaluation.

Common Pitfalls

Delaying diagnosis, manual detorsion, or surgical intervention.

- Reliance on a single "classic" differentiating parameter, such as age, onset of pain, physical examination findings (including the cremasteric reflex); or imaging findings can erroneously convince the examiner that testicular torsion is not present.
- Delaying surgical consultation while awaiting ancillary testing.

- Accepting an alternative diagnosis by a consultant over the telephone.
- Misdiagnosis of epididymitis in cases of testicular tumor or testicular torsion.
- Dismissal of a newly developed hydrocele as a benign process may delay diagnosis of an underlying testicular malignancy.

CHAPTER 122
Penile Disorders

Douglas L. McGee

Disorders of the penis, including balanoposthitis, phimosis, paraphimosis, and priapism, require expeditious evaluation and treatment.

BALANITIS, PHIMOSIS, AND PARAPHIMOSIS

Balanitis (inflammation of the glans penis) and *posthitis* (inflammation of the prepuce of the penis) usually occur together, and are referred to as *balanoposthitis* when they do. Balanitis is more common in uncircumcised men who exercise poor hygiene, but also affects young boys. Patients with balanoposthitis have an edematous, erythematous, fissured, and painful prepuce and glans. A variety of skin changes are possible, depending on the etiology (Table 122.1).

TABLE 122.1
Causes of Balanoposthitis

Infectious	Noninfectious
Fungal: *Candida albicans:* itching, burning, white discharge, discrete ulcerated papules, white, cheesy plaques	**Trauma**
Bacterial: group B streptococci, *Gardnerella vaginalis*, and mixed anaerobes	**Allergic:** latex allergy
STD-related: secondary syphilis, *Trichomonas vaginalis* genital herpes, condyloma lata, human papillomavirus	**Dermatologic:** psoriasis, lichen planus, erythema multiforme, premalignant, malignant lesions
Other: amoebiasis	

When the foreskin is not retractable behind the glans penis, the condition is termed *phimosis*. Physiologic phimosis is present until normal adhesions between the foreskin and glans have separated. Although most young boys are able to retract the foreskin by puberty, retraction is usually possible at an earlier age (1). As normal secretions accumulate and epithelial sloughing occurs, smegma is normally formed and assists in the separation of the foreskin from the glans. Parents may confuse smegma with infectious discharge if expressed from the penis. Pathologic phimosis, or simply phimosis, occurs when retraction of the foreskin is not possible after puberty or when the foreskin was previously retractable. When balanoposthitis is severe, phimosis may occur and precipitate urinary retention.

Paraphimosis occurs when the retracted foreskin is not replaced, usually after cleansing or catheter insertion. After foreskin retraction, the constricting phimotic ring causes progressive edema and impairs venous return, threatening the viability of the glans. Although most patients complain of pain and usually provide a history of foreskin retraction, debilitated uncircumcised patients may not provide this history. History of circumcision may be available from medical records or from a caregiver. Do not confuse paraphimosis with balanitis in these patients.

ED EVALUATION

The emergency department (ED) evaluation for patients with balanoposthitis, phimosis, or paraphimosis is usually limited to the history and physical examination. Measure the patient's blood glucose when there is infection with *Candida albicans,* and perform serologic testing if secondary syphilis is suspected. Acetic acid whitens the superficial epithelial skin layer when applied to lesions infected with human papillomavirus (HPV). Determine if the patient can urinate when severe phimosis or paraphimosis is diagnosed.

ED MANAGEMENT

The mainstay of ED management of balanoposthitis includes meticulous hygiene, including retraction of the foreskin and cleansing of the glans penis and prepuce, but the aggressive use of soap to clean under the prepuce is not advisable. Treatment of infectious balanoposthitis is directed against the offending organism. Fungal infections of the glans are treated with topical antifungal agents, and metronidazole is appropriate for *Gardnerella* sp, anaerobic infection, and *Trichomonas* sp. Secondary syphilis, if suspected, is treated according to established guidelines.

Asymptomatic phimosis does not require emergent treatment. Reassure concerned parents when physiologic phimosis is present, and discourage forceful retraction. Several studies demonstrate that medium- or high-potency topical steroids applied to the foreskin for 4 to 6 weeks are 85% to 90% effective when retraction is desired (2,3). However, several studies comparing steroid cream with placebo moisturizing showed resolution of phimosis in slightly more than half of the placebo group (4,5). When severe phimosis causes urinary retention or interferes with placement of a urinary catheter, a slit made in the dorsal aspect of the foreskin facilitates access to the urethral meatus (6). After providing local anesthesia of the penis with a dorsal nerve block or ring block placed at the base of the penis, gently separate adhesions between the foreskin and glans with a hemostat. Place one jaw of the hemostat inside the dorsal foreskin, taking care not to include the urethral meatus or glans. Close the hemostat to crush the foreskin for 3 to 5 minutes then

incise the crushed area with straight scissors. The crushed edges rarely bleed but may require absorbable suture for hemostasis if they separate. Although some patients are satisfied with the cosmetic appearance of the foreskin after the dorsal-slit procedure, a urologist may perform an elective circumcision at a later date. Always return the foreskin to the reduced position after urinary-catheter placement.

Paraphimosis requires emergent treatment. After adequate sedation or penile anesthesia, attempt manual reduction. A simple initial approach to paraphimosis is to wrap the edematous prepuce with an elastic bandage to provide gentle, nontraumatic compression that slowly forces edematous fluid under the phimotic ring (7). Self-adhering bandages facilitate continuous compression. Wrap the phallus, starting at the glans with 3 to 4 wraps of compression bandage and leave in place for 20 minutes. Marked reduction in edema has resulted in autoreduction or may facilitate other methods of manual reduction if paraphimosis persists after compression. Place the fingers of both hands distal to the phimotic ring and foreskin and apply gentle, steady pressure on the glans with the thumbs (6). Gauze placed under the fingers may improve traction on the foreskin while bringing it over the glans, but lubricants are rarely helpful. Several other techniques are described to treat paraphimosis; application of these techniques are guided by the physician's skill and training in the maneuvers. A 21-gauge needle may be used to puncture the edematous foreskin. Manual compression after puncture may allow the escape of enough edema fluid to facilitate reduction (7,8). Repeated punctures or blood aspirated from the engorged glans after a tourniquet is placed at the base of the penis may also allow reduction (9,10). Subdermal hyaluronidase (1 mL) injected into the edematous foreskin facilitates dispersion of edema fluid and may make reduction possible (11). Some recommend the application of granulated sugar to the edematous glans and foreskin to extract tissue water, reduce edema, and ease reduction (12). Gauze soaked in 20% mannitol wrapped around the edematous prepuce for 30 to 45 minutes may

also facilitate reduction (13). When less aggressive methods fail, incise the phimotic ring to facilitate foreskin reduction (6).

CRITICAL INTERVENTIONS

- Return the foreskin after urinary catheter insertion in uncircumcised males.
- Paraphimosis is a urologic emergency that must be relieved in the ED.

DISPOSITION

Most patients with balanoposthitis may be treated as outpatients. Some diabetics may require inpatient treatment if the infection is severe and the diabetes is poorly controlled.

When phimosis is present and causes urinary retention, consider urologic consultation to relieve phimosis and allow free drainage of urine if a urinary catheter cannot be placed.

Emergent urology consultation is necessary if paraphimosis cannot be successfully relieved in the ED. Patients in whom paraphimosis has been successfully relieved require follow-up with their primary physician and may benefit from future circumcision.

Refer patients with skin lesions suspicious for precancerous changes or malignancy to a dermatologist for further evaluation.

Common Pitfalls

- Phimosis is normal in young boys and does not require treatment in asymptomatic adults.
- Paraphimosis, a urologic emergency, can be confused with balanitis unless it is recognized that the foreskin is retracted.
- Always return the foreskin its anatomic location after retraction.

PRIAPISM

Priapism is characterized by a prolonged, painful, unwanted penile erection, usually in the absence of sexual stimulation. The physiologic balance achieved between venous outflow and arterial

dilatation of the corpora cavernosa controls erectile function. Priapism occurs when normal physiologic blood flow is altered disrupting this balance. Medications used to treat erectile dysfunction in men (sildenafil, papaverine, prostaglandin E1, etc.) are responsible for most cases of priapism (12). It is uncommon in boys, unless sickle cell disease is present, and it is rare in neonates (14). Henoch–Schönlein purpura is described as another cause of priapism (15). Patients with priapism complain of penile pain and persistent erection, even after ejaculation. The mean time to presentation in one series of 34 patients was 30 hours (16).

Priapism may be divided into "low-flow" and "high-flow" types (16). Low-flow priapism results from abnormal venous outflow, whereas high-flow priapism results from abnormally increased arterial inflow. Low-flow priapism is more common and is often caused by vasoactive drugs that cause engorgement of the corpora cavernosa. Impaired venous outflow causes sludging, thrombosis, acidosis, ischemia, and decreased oxygen tension within the corporal bodies. This pathophysiologic cascade causes the irreversible cellular damage and corporal fibrosis responsible for the long-term complications of low-flow priapism. Oral and intracavernosal agents used for erectile dysfunction, antihypertensive agents, psychotropic drugs, cocaine, and ethanol are among the drugs that have been implicated. Leukemia, sickle cell anemia, and a variety of neoplastic etiologies are also responsible for low-flow priapism (16). High-flow priapism is uncommon and usually results from trauma to the penis or perineum (17). Arterial fistula formation between the cavernosal artery and the corporal bodies increases arterial flow into the penis that exceeds venous outflow.

ED EVALUATION

The etiology of priapism can usually be ascertained with careful questioning. Determine the onset of erection and history of prior episodes of priapism. Pay careful attention to prescription or illicit drug use to help determine whether these agents are responsible.

Sickle cell disease may be causative in patients at risk or known to have this disease. The penis is erect and painful to palpation. The corpora cavernosa is engorged and tender to palpation, but in contrast to normal erections, the corpus spongiosum (erectile tissue surrounds the urethra) and glans penis are usually flaccid.

Some authors recommend blood-gas analysis of blood aspirated from the corporal bodies to assist in differentiating between low- and high-flow states (16,17). Low pH, low oxygen tension, and high carbon dioxide levels suggest low-flow priapism, caused by venous obstruction. Blood-gas parameters similar to arterial blood suggest high-flow priapism, a condition usually seen after trauma. Because nearly all cases of priapism are low flow, and trauma is usually associated with high-flow priapism, differentiating between the two is not difficult in most cases, making blood gas analysis unnecessary. Doppler flow ultrasonography of the penis and perineum can be used to document arteriovenous fistulas when high-flow priapism is suspected (17). However, treatment of low-flow priapism should *not* be delayed pending ultrasonography.

ED MANAGEMENT

The ED management of priapism includes both pharmacologic and mechanical treatment options. Untreated ischemic priapism may result in permanent erectile dysfunction. Consider analgesia and sedation to facilitate detumescence. There is conflicting literature describing the efficacy of terbutaline in priapism. Some small clinical trials demonstrate that oral terbutaline is more effective than placebo in achieving detumescence (18), but others have found no benefit (19). Because of its relative safety in patients without hypertension or coronary artery disease, a trial of subcutaneous terbutaline (0.25 to 0.5 mL injected subcutaneously, repeated in 20 minutes if needed) or oral terbutaline (5 mg repeated in 15 minutes) may be attempted (17).

When sedation, analgesia, or terbutaline do not result in detumescence, corporal aspiration and irrigation is indicated (16,17). The penis is anesthetized, and 30 to 60 mL of blood is

aspirated from a single corporal body at the 10 o'clock or 2 o'clock position after puncture with an 18- to 20-gauge needle; anastomoses between the corporal bodies obviate the need for bilateral aspiration. Do not puncture the glans. If the erection persists after aspiration, phenylephrine is carefully injected into the punctured corpus cavernosum. One milligram of phenylephrine is diluted in 9 mL of sterile saline to achieve a concentration of 100 μg/mL, and 100 to 200 μg aliquots of phenylephrine are injected up to three times to achieve detumescence. Monitor blood pressure and cardiac rhythm when repeated injections are required.

Sickle cell patients with priapism require analgesia, hydration, and supplemental oxygen but are also treated with the methods described above. Red blood cell exchange transfusion has been employed when traditional antisickling measures fail, but there is no evidence to support its efficacy (20,21). Emergent ED therapy is not required for high-flow priapism because it does not cause the ischemic injury seen in low-flow priapism.

CRITICAL INTERVENTIONS

- Treat patients with low-flow priapism with terbutaline, corporal aspiration, and/or phenylephrine injection.
- Priapism is a urologic emergency that requires ED treatment in coordination with the consulting urologist.

DISPOSITION

Patients with priapism may be discharged home to follow-up with an urologist after detumescence is accomplished in the ED. When ED treatment fails to relieve the erection or when high-flow priapism is suspected, urgent urologic evaluation is necessary.

Common Pitfalls

- Failure to obtain an adequate history to determine the etiology of priapism.
- Failure to achieve detumescence of priapism prior to discharge.

CHAPTER 123 Urinary Tract Infection

Lara Kulchycki

Urinary tract infections (UTIs) are among the most common infections encountered by the emergency physician. Women younger than age 50 are affected disproportionately; young, sexually active women are 30 times more likely than their male contemporaries to have a UTI (1). Fifty percent to 70% of women will have a UTI at some time in their lives, placing the annual incidence between 3% and 10% (1,2). Although UTIs are reported in 15% of men prior to age 35 years, they are much more common later in life as disorders of the prostate become more prevalent (3). The incidence of UTI increases with age, affecting elderly men and women with nearly equal frequency.

UTI can be classified by the site of disease and risk of complications. Anatomically, they are divided into upper tract infections of the kidney (pyelonephritis) and lower tract infections of the bladder (cystitis). UTIs can be further classified as complicated when associated with conditions that increase the risk of infection, treatment failure, or morbidity. There are multiple factors associated with complicated infection, including urinary obstruction, indwelling bladder catheterization, ureterolithiasis, pre-existing renal disease, immunosuppression, and pregnancy (Table 123.1). Complicated UTIs can range in severity from simple cystitis to septic shock; it is the associated conditions, not disease severity, that make a UTI "complicated." It is generally held that all UTIs in men are complicated and that true uncomplicated infections occur only in nonpregnant, healthy adult women (4). These classifications have

clinical relevance, as the distinctions have important implications for treatment and disposition.

TABLE 123.1
Risk Factors for Development of Complicated UTI

Anatomic obstruction	Urinary retention/increased postvoid residual
Bladder diverticulum	Immunosuppression
Nephrolithiasis	Chronic renal failure
Other renal structural abnormality	Diabetes mellitus
Polycystic kidney disease	Drug or alcohol abuse
Prostatic hypertrophy	HIV/AIDS
Solitary kidney	Organ transplantation
Urethral/ureteric stricture	Sickle cell anemia and trait
Epidemiologic	Steroids/Immunosuppressant drugs
Age >55 years	Instrumentation
Childhood UTI (prior to age 12 yrs)	Indwelling catheter
Hospitalization	Intermittent catheterization
Male	Ureteric stent
Pregnancy	Other
Functional	Prolonged symptoms prior to treatment (>7 d)
Incontinence	Resistant etiologic organisms
Neurogenic bladder	Treatment failure

UTI, urinary tract infection; HIV, human immunodeficiency virus; AIDS, acquired immunodeficiency syndrome.
Developed from information in articles by Bass PF 3rd, Jarvis JW, Mitchell CK. Urinary tract infections. *Prim Care.* 2003;30:41–61; Krieger JN. Urinary tract infections: What's new? *J Urol.* 2002;168:2351–2358.

The vast majority of UTIs, approximately 95%, result from ascending infection by enteric bacteria (1). The urinary tract is normally an enclosed, sterile system. Bacterial washout by urine flow is the primary host defense against infection, and any interference with this process predisposes an individual to UTI. The remaining 5% of UTIs result from hematogenous spread (1). These infections tend to occur in immunocompromised hosts and can be aggressive, causing severe pyelonephritis or renal abscess (5). The female urinary tract is prone to colonization with enteric bacteria, given the

close proximity of the urethra to the rectum, the moist mucosa surrounding the introitus, and the relatively short (3 to 4 cm) female urethra. The primary risk factors in young healthy women are recent sexual intercourse, use of a spermicide-containing contraceptive, and prior UTI (1,6,7).

The male genitourinary tract is less conducive to colonization and infection. The male urethra is longer, distant from the perineum, and surrounded by dry squamous epithelium (8). As most UTIs occur in older men, these infections are probably the result of incomplete bladder emptying or instrumentation of the genitourinary tract related to prostatic hypertrophy (4). Additional risk factors in healthy men include a lack of circumcision, anal intercourse, a sexual partner with the same uropathogen, and anatomic abnormalities, such as urethral strictures (4,8,9).

Asymptomatic bacteriuria (ASB) is simply the presence of bacteriuria in a patient without UTI symptoms. It is typically defined by a positive urine culture. ASB occurs in only 5% of healthy young women, but the incidence increases with age to as high as 40% in women older than 60 (3,10). Rates of ASB in elderly men are similar. ASB is more common in certain patient populations, such as patients with diabetes, spinal cord injury, indwelling catheters, and those undergoing hemodialysis (11). Although 30% of individuals with ASB develop symptomatic UTI within 1 year, clinical studies show little utility in making the diagnosis except in selected patient populations, most notably pregnant women (10–12).

The organisms responsible for UTIs are largely enteric bacteria. The most common uropathogens are enteric gram-negative bacilli of the class Enterobacteriaceae. *Escherichia coli* is responsible for 80% to 90% of UTIs in reproductive-aged females. *Staphylococcus saprophyticus* causes an additional 5% to 20% of UTIs in this group (10). Other causative organisms include *Proteus, Klebsiella, Citrobacter, Pseudomonas, Enterobacter, and Enterococci.* Institutionalized, catheterized, and immunosuppressed patients tend to develop UTIs caused by gram-positive cocci, Enterobacteriaceae species, and *Candida* (3).

The relative virulence of pathogens differs between complicated and uncomplicated UTIs. Bacterial virulence is crucial for overcoming defenses in the normal host (7). Uropathogenic bacteria are highly adapted to ascend, colonize, and proliferate in the normally sterile urinary tract. In contrast, virulence is less important in complicated UTIs, as host factors largely determine the risk of infection and clinical course (7). Organisms that rarely cause disease in healthy patients can cause significant morbidity in hosts with anatomic, metabolic, or immunologic abnormalities.

Recurrent UTI is defined as three or more episodes of UTI within 1 year. It occurs in 20% to 30% of women with acute cystitis, usually as the result of discrete uncomplicated infections (2). Recurrent infections in premenopausal women are generally not associated with underlying health problems or anatomic abnormalities. However, such patients should be identified for consideration of antibiotic prophylaxis (10). Postmenopausal women with recurrent UTI have higher postvoid residual volumes and reduced urinary flow when compared with age-matched controls (13). These patients may benefit from vaginal estrogen therapy (13). The most common cause of recurrent cystitis in men is chronic bacterial prostatitis.

CLINICAL PRESENTATION

Acute Cystitis

Symptoms of acute cystitis typically include dysuria, frequency, urgency, and suprapubic discomfort. However, patients may present solely with vague complaints, such as chills, malaise, and myalgias. Hematuria commonly occurs. Fever ($>38^{\circ}C$) and severe abdominal pain are rare and should prompt the emergency physician to consider upper tract disease or an alternative diagnosis.

Symptomatic Catheterized Patients

Urinary catheterization is responsible for most cases of nosocomial UTI. The incidence of infection for those with indwelling catheters is 5% per catheter-day (5). Such UTIs are, by definition, complicated,

with manifestations ranging from suprapubic pain, bladder spasms, and incontinence around the catheter to fulminant sepsis.

Acute Pyelonephritis

Acute pyelonephritis can present with variable severity, from a mild cystitis–like illness with flank pain to a more severe illness with fever, rigors, and vomiting. The absence of cystitis symptoms is common (10).

Sepsis

Sepsis in the setting of UTI is most likely to manifest in patients with indwelling catheters, immunosuppression, urinary obstruction, advanced age, or serious underlying medical problems. Elderly patients from extended care facilities are at greatest risk, where the rate of bacteremia from UTI approaches 60% (3). Such patients often present with nonspecific symptoms, including fever, confusion, dehydration, and generalized weakness (3).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute dysuria in emergency department (ED) patients includes primarily infectious and structural disorders. Infectious causes include urethritis, cystitis, pyelonephritis, vulvovaginitis, prostatitis, and epididymoorchitis. Structural causes of dysuria include local trauma, urethral strictures, urethral prolapse, prostatic hypertrophy, and genitourinary neoplasms. Other potential etiologies include vaginal atrophy secondary to hypoestrogenism, reactive arthritis (Reiter syndrome), vasculitis (Behçet syndrome), interstitial cystitis, and various psychogenic conditions.

The flank pain of pyelonephritis can occur with other disease processes. Patients with unilateral costovertebral angle tenderness may have a renal calculus, perinephric abscess, renal infarct, neoplasm, or traumatic injury. Flank pain may be a presenting symptom in vascular, neuromuscular, and pulmonary disease; potential etiologies include abdominal aortic aneurysm,

radiculopathy, muscular back pain, herpes zoster, lower lobe pneumonia, and pulmonary embolism.

ED EVALUATION

The emergency clinician should inquire about the presence and duration of urinary symptoms, such as dysuria, urgency, frequency, suprapubic pain, gross hematuria, foul-smelling urine, nocturia, poor urinary stream, and incontinence. Symptoms of upper tract disease should be sought, including high fever, vomiting, and flank or back pain. Physicians should ask whether the patient has external genital lesions, vaginal complaints, penile discharge, or testicular pain. A detailed sexual history including the possibility of pregnancy, nature of sexual practices, and method of birth control is also prudent. Finally, the patient's medical history should be explored to identify any criteria for complicated UTI (see Table 123.1).

Patient history can help the clinician differentiate between cystitis and urethritis. The urgency, frequency, and incontinence from bladder spasms, which often accompany the dysuria of acute cystitis, are uncommon in isolated urethritis. Urethritis generally presents with a more gradual onset in patients with concomitant vaginal or penile discharge.

The physical examination begins with an assessment of vital signs, general appearance, and hydration status. Examination of the genitourinary tract includes assessment for costovertebral angle tenderness, suprapubic mass or tenderness, and abnormalities of the external genitalia. A pelvic examination should be performed in women if the diagnosis is unclear or the symptoms suggest urethritis or vaginitis. A complete penile, testicular, and prostate examination is necessary in men to differentiate UTI from urethritis, epididymoorchitis, and prostatitis. Clinicians should exercise caution in the evaluation of pediatric (see Chapter 290) and geriatric patients, as they may lack localizing symptoms and signs.

A urine specimen should be collected by the method most appropriate for the patient's clinical status and capacity to cooperate with cleansing guidelines. For most alert, cooperative patients, a clean catch urinalysis can be utilized. The sample should be a

midstream specimen obtained after perineal or penile cleansing. In the presence of poor hygiene, morbid obesity, menstrual blood, copious vaginal discharge, or an anatomic abnormality, the preferred method for obtaining a urine specimen is an in-and-out urethral catheterization of the bladder. The main risk of catheterization is induction of UTI, but this occurs in less than 1% of healthy hosts (14). All specimens should be processed promptly after collection, as stagnation increases colony counts.

Urine dipstick testing relies on nitrite and leukocyte esterase testing to detect infection. The nitrite test depends on bacterial reduction of endogenous nitrates to nitrites and is more likely to be positive in the presence of gram-negative bacteria. The nitrite test may be falsely negative with low-count UTIs, urinary dilution, concurrent antimicrobial therapy, and infections caused by nonnitrate-reducing bacteria (1,15). Although the sensitivity of the nitrite test for culture-confirmed UTI ranges from 19% to 48%, the specificity is 92% to 100% (16). Therefore, a positive nitrite test strongly suggests infection, whereas a negative test does not exclude it. The leukocyte esterase test detects the presence of neutrophil granules and implies pyuria of greater than 8 to 10 white blood cells per high-power field. The sensitivity for the leukocyte esterase test ranges from 72% to 97%, whereas the specificity is 41% to 86% (16). False-positive leukocyte esterase results have been reported with contaminated urine samples or *Trichomonas* infection. Sterile pyuria is also possible, for example, in appendicitis. False-negative results can occur in urine containing glucose or ketones (16). The combination of negative nitrite and leukocyte esterase testing has a negative predictive value of 0.98 (17).

A normal dipstick analysis may obviate the need for urine microscopy. In 95% of cases, negative dipstick testing corresponds to a normal microscopic evaluation (18). As microscopy rarely changes therapy in this case, physicians must consider both the time delay and cost of the test. Full microscopic evaluation may be of assistance in cases where false-negative or false-positive results are expected.

The isolation and quantification of uropathogens in culture can be used to diagnose infection and guide clinical therapy. Traditionally, a

culture must exceed 10^5 colony-forming units (CFU) per mL of urine to confirm infection. However, clinical studies have found this threshold too stringent; 30% to 50% of patients with symptomatic UTI fail to grow 10^5 CFU/mL (15). Early infection, partially treated UTI, use of diuretics, recent voiding, or urinary obstruction may explain these low-count UTIs (15). In a clinical context suggestive of infection, bacterial growth exceeding 10^3 CFU/mL may be sufficient. Symptomatic catheterized patients with counts greater than 10^2 CFU/mL should also be considered infected. This reduced threshold for positive culture still allows clinicians to differentiate UTI from other causes of dysuria (10).

The vast majority of young, healthy women with UTI do not need urine cultures or antibiotic sensitivity testing. Cultures should be obtained in women with a complicated UTI, acute bacterial pyelonephritis, persistent fever of unknown origin, relapsing UTI, neutropenic fever, UTI in the setting of indwelling bladder catheterization or urethral stents, nosocomial urinary infections, or sepsis (19). Cultures may also prove useful in patients with a history that is strongly suggestive of UTI, but an inconclusive physical examination and urinalysis. Because UTIs in men are, by definition, complicated, more conservative evaluation with urine culture is warranted. Although culture results are not available to guide initial ED management, they can be of value to subsequent clinicians caring for the patient.

Additional laboratory studies should be tailored to the patient's history and clinical presentation. Individuals at risk for acute renal failure, such as patients with sepsis, urinary obstruction, or renal transplantation, should have the serum creatinine measured in the ED. If urogenital infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae* is suspected, cervical cultures, urethral swabs, or first-void urine testing should be performed. Pregnancy testing is indicated for all women capable of childbearing. Blood cultures should not be routinely performed in patients selected for outpatient treatment. Although blood cultures are positive in 18% to 29% of patients with pyelonephritis, the results rarely ($<2\%$) affect antimicrobial therapy, as the causative organism can be obtained

from urine culture (20). In adults, blood cultures may be useful when the diagnosis is unclear, a urine culture cannot be obtained, or bacteremic seeding of the kidneys is suspected.

Radiologic imaging is generally unnecessary in the ED evaluation of patients with UTI, as such studies rarely alter the therapeutic approach (4). Routine imaging of women with pyelonephritis is also not recommended, because the majority of these patients have normal anatomy. In contrast, radiologic imaging of young men with even a single urinary infection yields an anatomic abnormality in more than 30% of cases (4). Indications for emergent imaging are not clearly defined. Infected patients who are severely ill, have suspected obstructive urolithiasis or perinephric abscess, or fail to respond to antimicrobial therapy may require imaging with ultrasonography, computed tomography, or intravenous pyelography.

KEY TESTING

- Urinalysis and pregnancy testing
- Urine culture in patients with complicated UTI, pyelonephritis, or sepsis

ED MANAGEMENT

Acute Cystitis

Patients with uncomplicated acute cystitis can be treated as outpatients with oral antibiotics. As with all antimicrobial therapy, the choice of drug must be tailored to regional susceptibility patterns. Previous urine culture results, if available, maybe useful in agent selection. In vitro studies have found increasing resistance of common uropathogens to first-line agents (21,22). Despite this trend, trimethoprim–sulfamethoxazole (TMP–SMX) remains an excellent first-line agent in regions with a resistance rate less than 20% (3,22). Even patients with culture-proven resistance may achieve clinical cure because of the high urinary concentrations of this agent (1,3,6). Fluoroquinolones or nitrofurantoin remain viable alternatives. Three-day regimens offer comparable efficacy to longer courses (22).

However, if a patient is being treated with nitrofurantoin, a 7-day regimen tends to be more effective. (1,22). Single-dose therapy with fosfomycin tromethamine has been described, but cure rates are lower than with standard agents (23). Beta-lactam antibiotics cannot be recommended as first-line agents, given the high incidence of drug resistance (23). A urinary analgesic, such as phenazopyridine, may be given for symptomatic relief. See Table 123.2 for alternative antimicrobial regimens.

TABLE 123.2
Treatment Regimen for Urinary Tract Infections

Condition	Characteristic Pathogens	Recommended Treatment	Recommended Duration of Treatment
Acute uncomplicated cystitis	*Escherichia coli, S. saprophyticus, Proteus mirabilis, Klebsiella pneumoniae*	Trimethoprim/sulfamethoxazole (TMP–SMX) 160 mg/800 mg bid	3 d
		OR	
		Fluoroquinolones: ciprofloxacin 500 mg bid, ofloxacin 200 mg bid, levofloxacin 250 mg daily	3 d
		OR	
		Cefixime 500 mg daily	3 d
		OR	
		Nitrofurantoin (Macrobid) 100 mg bid	7 d
Recurrent cystitis	*E. coli, S. saprophyticus, P. mirabilis, K. pneumoniae*	Consider prophylaxis with: TMP–SMX 40/200 mg, nitrofurantoin 50 mg, norfloxacin 200 mg, cephalexin 250 mg, trimethoprim 100 mg daily	6 mos
		OR	
		Consider postcoital prophylaxis with TMP–SMX 40/200 mg	
Complicated urinary tract infection (outpatient therapy)	*E. coli, Proteus* species, *Klebsiella* species, *Pseudomonas* species, *Serratia* species, *Enterococci, Staphylococci*	Fluoroquinolones: ciprofloxacin 500 mg bid, ofloxacin 200 mg bid, levofloxacin 250 mg daily	7–10 d
Asymptomatic bacteriuria in pregnancy	*E. coli, S. saprophyticus, P. mirabilis, K. pneumoniae*	Nitrofurantoin (Macrobid) 100 mg bid	3 d
		OR	
		Cephalexin 250–500 mg qid	3 d
		OR	
		Fosfomycin 3 g sachet once	Single dose
Acute pyelonephritis, uncomplicated (outpatient treatment)	*E. coli, S. saprophyticus, P. mirabilis, K. pneumoniae*	Consider IV loading with:	10–14 d
		Gentamicin 3–5 mg/kg, or ceftriaxone 1 g, followed by:	
		Fluoroquinolones: ciprofloxacin 500 mg bid, ofloxacin 200 mg bid, Levofloxacin 250 mg daily	
		OR	
		TMP–SMX (160 mg/800 mg) bid	10–14 d
Acute pyelonephritis, severe (requiring hospitalization)	*E. coli, S. saprophyticus, P. mirabilis, K. pneumoniae*	Gentamicin 5 mg/kg IV daily	Daily until clinically improved, followed by 10–14 d of oral therapy above
		OR	
		Ceftriaxone 1 g IV daily	
		OR	
		Fluoroquinolones: ciprofloxacin 500 mg IV bid, ofloxacin 200–400 mg IV bid, levofloxacin 500 mg IV daily	
Complicated urinary tract infection or Urosepsis (severe illness requiring hospitalization)	*E. coli, Proteus* species, *Klebsiella* species, *Pseudomonas* species, *Serratia* species, *enterococci, staphylococci*	Gentamicin 5 mg/kg IV daily plus ampicillin 1 g IV q 6h	Daily until clinically improved, followed by 10–14 d of oral therapy above
		OR	
		Ceftriaxone 1 g IV daily	
		OR	
		Ticarcillin–clavulanate 3.2 g IV q8h	
		OR	
		Imipenem–cilastatin 250–500 mg IV q6–8h	
		OR	
		Fluoroquinolones: ciprofloxacin 500 mg IV bid, ofloxacin 200–400 mg IV bid, levofloxacin 500 mg IV daily	

Recurrent Urinary Tract Infection

Women with more than three UTIs within 1 year may benefit from prophylactic therapy. Postcoital antibiotic prophylaxis may benefit women whose recurrences are related to intercourse (2,3,21). Continuous daily antibiotic prophylaxis for 6 months with TMP–SMX, nitrofurantoin, norfloxacin, cephalexin, or trimethoprim has also been shown to decrease morbidity from recurrent UTIs (2,13,21). Potential side effects from these regimens include vaginal candidiasis and gastrointestinal symptoms. Unfortunately,

approximately 40% to 60% of these women can be expected to reestablish their pattern of frequent infections within 6 months of discontinuing antibiotics (3). Postmenopausal women with recurrent UTI may benefit from vaginal estrogen therapy, which can also ease the symptoms of atrophic vaginitis (13,24).

Much traditional teaching that emphasizes behavioral modification to reduce the risk of recurrent UTI has not been supported in studies. Specifically, the volume of fluid intake, timing of voiding relative to intercourse, and direction of wiping after voiding have no proven benefit (13). Clinical data on the consumption of cranberry products and lactobacillus probiotics are inconclusive or conflicting (13,25).

Men with recurrent cystitis have an increased incidence of chronic bacterial prostatitis (see Chapter 124). These patients will require a longer course of antibiotics and should receive follow-up with a urologist.

Pyelonephritis

The treatment for pyelonephritis is based on the nature and severity of symptoms. Patients who are febrile and vomiting should receive antipyretics, antiemetics, and intravenous fluids. Some authors advocate the use of single-dose parenteral therapy followed by oral therapy for 10 to 14 days (1,3,7). Acceptable parenteral agents include gentamicin and third-generation cephalosporins. Gentamicin offers the advantage of high urinary concentrations, efficacy against common uropathogens, and a low side effect profile with single-dose therapy (1). Nitrofurantoin is not a recommended agent for upper tract infections, as it may lack sufficient tissue penetration to eradicate disease in the kidney. Because up to 10% of patients develop worsening symptoms within 24 to 36 hours of ED discharge, early follow-up is recommended (1,3). Failure to improve within 48 to 72 hours often signals complicated infection and should prompt further evaluation.

Complicated Urinary Tract Infection

Because of the predisposing conditions in complicated infections, a longer course of therapy and closer follow-up are warranted to ensure a cure. Acceptable agents are listed in Table 123.2. Treatment should consist of a 7- to 10-day course of a fluoroquinolone or TMP–SMX (1,3,4,8). Nitrofurantoin should be avoided in men, given its inability to eradicate organisms in the prostate.

Urinary Tract Infection Complicating Pregnancy

Urinary infections in pregnant women warrant special attention as they require careful antibiotic selection and obstetric follow-up. Many antibiotics commonly used to treat UTIs are contraindicated in pregnancy, such as TMP–SMX and fluoroquinolones. Viable alternatives for treating the parturient include nitrofurantoin and cephalexin (3). A 7- to 10-day course of treatment is recommended for cystitis and a 14-day course for pyelonephritis (1,3). Consultation with the patient's obstetrician is necessary in cases of pyelonephritis.

Asymptomatic Bacteriuria

Treatment of ASB is not advocated except in selected patients at risk for complications (11). Pregnant women with ASB warrant a course of antimicrobial therapy. Although ASB occurs in only 4% to 7% of pregnant women, it is associated with serious maternal and fetal health threats. If untreated, 30% of such women will develop pyelonephritis, a condition associated with an increased risk of amnionitis, premature labor, low–birth-weight infants, and pregnancy-induced hypertension (1,12,22). Recommended ASB treatment regimens include 3 to 7 days of amoxicillin, an oral cephalosporin, or nitrofurantoin (see Table 123.2). Patients scheduled for invasive genitourinary procedures, not including routine catheter changes, should also receive a dose of antibiotics prior to the procedure to decrease the risk of bacteremia. According to Infectious Diseases Society of America (IDSA) Guidelines, there is no evidence to support ASB screening and treatment in patients with immunosuppression, organ transplantation, spinal cord injury, or indwelling catheters (11).

Sepsis

Septic patients require rapid identification and immediate resuscitative efforts. Airway assessment, supplemental oxygen, intravenous crystalloid, early antibiotics, and the judicious use of pressors are the main components of care. Although urine and blood cultures should ideally be obtained prior to antibiotic administration, the acquisition of samples for culture should not delay appropriate therapy. Examples of suitable antibiotics include a third-generation cephalosporin, imipenem–cilastatin, ticarcillin–clavulanate, or ampicillin in combination with an aminoglycoside (see Table 123.2).

CRITICAL INTERVENTIONS

- Identify complicated UTIs and select the antimicrobial agents and duration of therapy accordingly.
- Initiate early parenteral antimicrobial therapy in the patient with sepsis.

DISPOSITION

The involvement of consultants is unnecessary for most patients discharged from the ED with a diagnosis of UTI. Women with uncomplicated cystitis do not require follow-up unless symptoms persist or worsen. Cases of acute pyelonephritis may be referred to primary care physicians for subsequent management. Because of the high incidence of maternal and fetal complications, pyelonephritis in pregnancy has historically been treated as an inpatient (12). However, recent studies suggest that carefully selected women may be managed as outpatients with close obstetric follow-up (1,10,12). Men who develop cystitis prior to age 35 and men older than 50 with recurrent infections should be referred to an urologist (4). Finally, all patients with UTI in the setting of ureterolithiasis warrant urologic consultation in the ED.

Patients with UTI require admission if they have sepsis, severe pyelonephritis, or acute renal failure. Other candidates for admission are those with serious comorbidities, significant dehydration, intractable vomiting, severe pain, or failed outpatient management

(3). Older patients can exhibit striking mental status changes with UTI, and these individuals also require admission.

Common Pitfalls

- Failure to differentiate complicated from uncomplicated UTIs.
- Failure to consider UTI in pediatric or geriatric patients with nonspecific symptoms.
- Failure to perform a pelvic or genitourinary examination when indicated.
- Failure to collect an uncontaminated urine specimen or to recognize a contaminated one.
- Failure to consider local uropathogen susceptibilities in choosing antibiotics.
- Failure to ensure appropriate and timely follow-up.

CHAPTER 124
Prostatitis

Herbert G. Bivins

Prostatitis is the term used to describe a variety of inflammatory conditions of the prostate. Prostatitis may occur at any age but usually occurs between the second and fifth decades of life (1). Prostatitis is the most common urologic diagnosis in men younger than 50 years of age and the third most common urologic disorder in men older than 50. It is estimated that the US National Ambulatory Survey that prostatitis accounts for approximately 1.5 million patient encounters annually (2,3). Despite being common, prostatitis is often difficult to diagnose, categorize, and treat.

Prostatitis is classified into four categories: I—Acute bacterial prostatitis; II—Chronic bacterial prostatitis; III—Chronic pelvic pain syndrome (CPPS), with or without inflammation. Category IV is termed asymptomatic inflammatory prostatitis and is a biopsy diagnosis, which will not be further discussed (4).

CLINICAL PRESENTATION

Acute bacterial prostatitis typically presents with fever, chills, malaise, and a tender prostate on examination. In addition, there may be pain in the perineum, rectum, testicles, or lower back. Systemic symptoms may be present and sometimes appear prior to the lower urinary tract symptoms of dysuria, frequency, and dribbling. There may be urinary retention secondary to bladder outlet obstruction from the inflamed, edematous prostate. Pain with ejaculation may occur as well as the finding of blood in the semen. Acute prostatitis generally occurs from migration of bacteria from

the urethra or bladder, through the prostatic ducts, and into the prostate. Acute prostatitis may also occur in patients with an indwelling Foley catheter, after instrumentation or catheterization of the urethra, or after prostatic biopsy (5). The typical presentation along with the clinical finding of an enlarged, tender prostate on physical examination is consistent with a diagnosis of acute bacterial prostatitis.

Chronic bacterial prostatitis is more common, and may present more subtly than acute prostatitis. Typically the patient is a middle-aged man with recurrent urinary tract infection. Patients may have perineal discomfort, frequency, urgency, or dysuria, or they may be asymptomatic. An incidental finding of bacteriuria, or pyuria, should alert the clinician to consider the diagnosis of chronic bacterial prostatitis. The prostate may be enlarged, tender, boggy, or normal. Chronic bacterial prostatitis may occur after an episode of acute prostatitis or without any recognized antecedent infection.

Chronic pelvic pain syndrome is more common than acute or chronic bacterial prostatitis, yet the etiology is unclear and may be multifactorial (6). Pain is the predominant presenting symptom and is usually located in the perineum, suprapubic area, penis, testicles, or lower back. Difficulty with urination (hesitancy, dribbling, frequency, and urgency) is also common (7). Symptoms may vary but need to be present for 3 months to be considered chronic.

DIFFERENTIAL DIAGNOSIS

On occasion, disorders of the lower back and abdomen may have presenting symptoms similar to those of prostatitis, but generally the differential diagnosis includes other disorders of the urinary tract and rectum (Table 124.1). Differentiating acute bacterial prostatitis from the chronic forms is not difficult. The history and physical examination usually confirm the diagnosis. Chronic forms of prostatitis may be difficult to differentiate. The gold standard for distinguishing among disorders of the urethra, bladder, and chronic prostatic syndromes has been the *Meares–Stamey four-glass test,* which is described later.

TABLE 124.1
Differential Diagnosis

Cystitis	Perineal abscess
Interstitial cystitis	Perirectal/perianal abscess
Urethritis	Proctitis
Epididymitis/orchitis	Pyelonephritis
Seminal vesiculitis	Urolithiasis
Benign prostatic hyperplasia	Vesicular calculi
Prostatic cancer	Sacroiliitis, discitis, osteomyelitis, piriformis muscle strain

ED EVALUATION

The diagnosis of acute bacterial prostatitis is usually obvious. Examination of the acutely inflamed prostate should be performed gently so as not to cause bacteremia. Massage of the prostate and catheterization of the urethra in acute bacterial prostatitis may cause bacteremia and should be avoided. Because urinalysis and urine culture are essential, it may be necessary to perform needle aspiration of the bladder if the patient is obstructed (2). Complete blood cell counts, electrolytes, and blood cultures are of little benefit unless the patient is toxic, immunocompromised, or other underlying medical conditions are present that require further laboratory analysis. Bacterial prostatitis occurs more often in patients with human immunodeficiency viral (HIV) infection. Signs and symptoms are the same but prostatic abscess formation is more common, and there may be unusual organisms such as *Haemophilus parainfluenzae* and *Cryptococcus neoformans* as the causative agents (8). The general incidence of prostatic abscess is low but should be considered if the prostate is fluctuant or cannot be examined because of severe pain, or if there is no response to therapy. The diagnosis may be confirmed by computerized axial tomography or transrectal ultrasonography (9,10). Other than to establish a diagnosis of prostatic abscess, there is little reason to image the prostate in the ED.

The diagnosis of chronic bacterial prostatitis should be considered in men with recurrent urinary tract infections, asymptomatic

bacteriuria, perineal discomfort, and other urinary tract symptoms. Traditionally the diagnosis was confirmed using the *Meares–Stamey four-glass urine test.* This test compares the first 10 mL of voided urine, a midstream urine sample, expressed prostatic secretions, and a postmassage urine specimen. The urine specimens are centrifuged and examined under high power for leukocytes, bacteria, fungal hyphae, red blood cells, and oval fat bodies. All four samples are sent for culture (11).

Distinguishing between the chronic forms of prostatitis is unnecessary in the ED. Not only is the four-glass urine test impractical in the ED, but a survey of urologists revealed that 34% of respondents never used the test and 47% rarely did, and treatment was not affected (12). There may be no difference of bacterial localization rates in prostatic specific specimens in men with CP/CPPS and controls (13). A two-sample urine test has been recommended as a simple replacement to the four-glass test (14). Midstream premassage urine and postmassage initial 10 mL urine samples are obtained. Microscopy and cultures categorize the majority of chronic prostatitis patients almost as accurately (91% sensitivity and specificity) as do prostatic secretions (eTable 124.1) (15).

eTABLE 124.1

III B	–	–	–	–	–	–

WBC, white blood cell.

KEY TESTING

- Urinalysis and culture. Further testing is unnecessary in most patients.

ED MANAGEMENT

Acute bacterial prostatitis can be a serious and potentially life-threatening disease. Treatment of the toxic patient requires parenteral antibiotics, adequate hydration, analgesics, and admission. Drug penetration of the normal prostate is complex and dependent on lipid solubility, degree of protein binding and ionization, size and shape of the molecule, and pH. With acute inflammation, there is an increase in prostatic permeability; therefore, acute bacterial prostatitis is generally responsive to a wide variety of antibiotic agents. A urine Gram stain may be helpful in guiding the initial therapy but the usual causes of infection are the Enterobacteriaceae gram-negative bacteria. *Escherichia coli* accounts for 65% to 85% of infections, and *Pseudomonas, Klebsiella, Proteus,* and *Serratia* sp account for 10% to 15%. *Enterococcus, Staphylococcus aureus,* and other gram-positive organisms may account for 5% to 10% of acute infections (16). There also have been recent reports of community-acquired methicillin-resistant *S. aureus* causing both acute prostatitis as well as prostatic abscess (17). In sexually active young men, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* must be considered. *Mycoplasma* and *Ureaplasma* have also been implicated as causes of prostatitis (18).

The most commonly used oral antimicrobials for bacterial prostatitis have been trimethoprim-sulfamethoxazole (TMP–SMX) and the fluoroquinolones (16). Since there is increasing resistance to commonly employed antibiotics, it is essential to obtain a urine culture prior to empiric therapy (19). In many areas of the United States, the resistance of *E. coli* to TMP–SMX is greater than 25% (20). Fluoroquinolones have been shown to be superior to TMP–SMX, and levofloxacin once a day (500 mg) for 28 days is as effective as ciprofloxacin (500 mg) twice a day for 28 days (15). A total of 4 to 6 weeks of antibiotics may be required, owing to decreasing tissue penetration of the prostate as the inflammation resolves. Patients who cannot tolerate oral medications, appear toxic, are immunocompromised, have urinary retention, or for whom outpatient therapy has failed should be admitted and treated

with parenteral broad-spectrum antibiotics. A cephalosporin or aminoglycoside should be given along with a fluoroquinolone or ampicillin. For those patients who have failed outpatient quinolone therapy, imipenem, cefoxitin, or amoxicillin/clavulanic acid is effective (19). Outpatient therapy for acute bacterial prostatitis should include a fluoroquinolone or TMP–SMX (21) (Table 124.2). Although most patients respond to therapy, complications may include chronic bacterial prostatitis, epididymitis, bacteremia, prostatic abscess, and metastatic spread of the infection.

TABLE 124.2
Treatment Recommendations

NIH Consensus Category	Antibiotic/Dosage
Category I (Acute Prostatitis)	
Inpatient: Parenteral cephalosporin + quinolone or aminoglycoside + ampicillin Continue oral antibiotics based on culture results for 4 wks	Ceftriaxone 1–2 g IV qd, OR Cefoxamine 1–2 g IV q6h–q8h, OR Gentamicin or tobramycin 3–5 mg/kg/d + Levofloxacin 500 mg PO/IV qd, OR Ampicillin 1–2 g IV q6h
Outpatient: Oral quinolone or TMP-SMX for 4–6 wks	Levofloxacin 500 mg PO qd, OR Ciprofloxacin 500 mg PO bid, OR TMP–SMX 1 PO bid (160/800 mg bid)
Category II (Chronic Prostatitis)	
Oral fluoroquinolone or TMP–SMX (based on local resistance) for 4–12 wks	Levofloxacin 500 mg PO qd, OR Ciprofloxacin 500 mg PO bid, OR TMP–SMX 1 PO bid (160/800 mg bid)
Category III (Chronic Pelvic Pain Syndrome)	
Treat with analgesics, sitz baths Consider antibiotics as in category II in combination with α-blockers	(tamsulosin 0.4 mg PO daily)

Chronic bacterial prostatitis is usually caused by the same organisms. Treatment strategies for chronic bacterial prostatitis include both full-dose prolonged antibiotic therapy for 4 to 12

weeks, or daily suppressive therapy (3). The decision to place the patient on suppressive therapy is best left to the urologist or primary care physician.

Management of CPPS is often difficult for the physician and frustrating for the patient. Although this condition may be noninfectious, some clinicians will treat the inflammatory subtype with a trial of antibiotics for the possibility of infections caused by *Chlamydia, Mycoplasma,* or *Ureaplasma* (17). A study that compared tissue cultures from prostate biopsy of asymptomatic controls to patients with CPPS demonstrated no statistical difference (20). One Canadian multicenter, randomized, placebo-controlled study demonstrated no difference in symptom improvement after 6 weeks of levofloxacin, as compared to placebo (22). Recent studies suggest that treatment of CPPS with α-blockers, antibiotics, and anti-inflammatory medications may be beneficial (23,24). Symptomatic treatment with Sitz baths and nonsteroidal anti-inflammatory medications may also be helpful. Allopurinol, hormones, botulinum toxin, muscle relaxants, exercise, and a variety of nontraditional therapies have been recommended for CPPS, but there is insufficient evidence to justify their routine use in the ED (21).

CRITICAL INTERVENTIONS

- Initiate parenteral antibiotic therapy for toxic patients with acute bacterial prostatitis.
- Empiric treatment of acute bacterial prostatitis should cover infection with gram-negative rods.

DISPOSITION

Toxic patients with acute bacterial prostatitis should be admitted to the hospital for parenteral antibiotics. Because outpatient treatment of both acute and chronic bacterial prostatitis is prolonged and based on urinalysis, culture results, and, in many cases, biopsy, it is important to involve the patient's urologist or primary care physician in management and follow-up decisions. Patients with CPPS should be treated symptomatically and referred to a urologist.

If subspecialty referral is not easily obtainable, a trial of antibiotics, α-blockers, and anti-inflammatory medications for patients with newly diagnosed CPPS is reasonable (23,24).

Common Pitfalls

- Digital massage of the prostate and urethral catheterization should be avoided in acute bacterial prostatitis.
- Failure to place a suprapubic catheter in the setting of bladder outlet obstruction from an acutely inflamed prostate.
- Imaging of the prostate in the ED is unnecessary except when an abscess is suspected.

CHAPTER 125

Fournier Gangrene

Gregory W. Hendey

Originally described in 1764 by Baurienne, perineal gangrene today bears the name of Jean-Alfred Fournier, a French dermatologist, who described a case in 1883 (1,2). Fournier gangrene is the most severe end of a spectrum of scrotal and perineal infections, ranging from cellulitis to abscesses to necrotizing gangrene. Primary abscesses of the scrotal skin may originate from infections of the hair follicles or sweat glands. These abscesses tend to be superficial and similar to those found elsewhere on the body. Deep scrotal and perineal infections usually arise, on the other hand, from infection of the urinary tract or scrotal skin or from perirectal disease. Urogenital sources include extravasation of infected urine caused by a urethral stricture or after urethral instrumentation. Superficial skin abscesses, if left untreated or inadequately treated, may spread along deep fascial planes. Anorectal sources tend to be deep-rooted abscesses that may have spread extensively by the time of diagnosis. Eventually, the tunica albuginea is penetrated, with spread to Buck fascia. Once Buck fascia is invaded, the next barrier is the Colles fascia. Infection may spread anteriorly along the Colles fascia to involve the scrotum.

Fournier gangrene is a type of necrotizing fasciitis characterized by the rapid spread of a severe subcutaneous infection, with massive scrotal and perineal induration and swelling, which progresses to scrotal wall necrosis within 24 hours if not recognized and treated. The morbidity and mortality of Fournier gangrene are high. Though early reports estimated the mortality to be as high as 80%, more recent reports are less than 40% (1,3). The usual age of affected

patients is 50 to 60 years, and diabetics and alcoholics are particularly at risk (1,4–7). The typical organisms include *Escherichia coli, Bacteroides fragilis, Clostridium* sp, and hemolytic streptococci, though community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) has been reported (4,8,9).

CLINICAL PRESENTATION

Deep scrotal abscesses and Fournier gangrene may present as generalized scrotal swelling. The onset may occur several days after instrumentation of a urethral stricture or in an inadequately treated diabetic with an initial superficial skin abscess. The patient may have a history of perirectal disease. Pain is usually intense, but initial physical examination of the affected area can be subtle. Eventually, fever and other constitutional symptoms emerge and may lead to hypotension and sepsis. Diabetic patients may present with ketoacidosis. The scrotum is usually edematous, indurated, erythematous, tense, and warm, with or without a localized area of fluctuance or necrosis.

DIFFERENTIAL DIAGNOSIS

Superficial scrotal skin abscesses seldom cause difficulty in diagnosis. A localized area of erythema with a smaller area of suppuration is found on examination. Most patients are afebrile and without constitutional symptoms. Superficial abscesses may be incised and drained under local anesthesia in the emergency department (ED).

Scrotal edema from congestive heart failure or lymphatic obstruction may appear similar to scrotal infection. Concomitant edema of the lower extremities, however, shifts the differential away from an infectious cause. Occasionally, edema of the scrotum occurs as a result of an allergic reaction, but the scrotum should not be tender to palpation, and the erythema and warmth are substantially less than those found in infectious causes. Cellulitis of the scrotum may present with significant edema, and the distinction from a deep abscess may be difficult. Severe cases of

epididymoorchitis may also present with scrotal induration that mimics a deep scrotal abscess or Fournier gangrene. Other skin conditions that may mimic Fournier gangrene include pyoderma gangrenosum and warfarin necrosis.

ED EVALUATION

Rapid diagnosis and treatment of bacteremia are the principles of the initial approach. When the diagnosis is clinically obvious, immediate treatment and consultation is warranted. In less apparent cases, bedside ultrasonography may be helpful in differentiating hernia, cellulitis, localized abscess, and gas collections in the scrotal wall to facilitate a more rapid diagnosis (10). Subcutaneous air may also be demonstrated on plain radiographs of the pelvis, on ultrasound, or on computed tomography (CT) scan, although this finding is not necessary to establish the diagnosis, which is largely clinical. If urethral obstruction is suspected as the inciting cause, a urethral catheter should be placed into the bladder. The rectum and perineum should be examined carefully for induration and fluctuance. Blood cultures and laboratory studies should be obtained in anticipation of surgery and postoperative critical care.

KEY TESTING

- CBC, electrolytes, lactate, blood cultures, type and screen
- Imaging as needed (plain films, ultrasound, CT scan) to make the diagnosis or define extent of disease

ED MANAGEMENT

Fournier gangrene requires aggressive medical resuscitation with intravenous (IV) fluids and broad-spectrum antibiotics, such as ampicillin/sulbactam (Unasyn) 3 g IV, ticarcillin/clavulanate (Timentin) 3.1 g IV, or piperacillin/tazobactam (Zosyn) 3.375 g IV, and Clindamycin 900 mg IV. Vancomycin 1 g IV should be added if MRSA is suspected.

These modalities should be instituted as soon as possible, while urologic consultation is obtained, and the operating room should be

alerted for emergency surgical debridement. Although aggressive resuscitation, supportive measures, and early antibiotics are important aspects of the initial emergency care for patients with Fournier gangrene, this is a surgical emergency, and the definitive care is operative. It is imperative to involve the surgeon early, without delaying for the results of laboratory or imaging studies. Surgical debridement tends to be extensive and often requires multiple procedures, including urinary and fecal diversions and skin grafting.

CRITICAL INTERVENTIONS

- Initiate fluid resuscitation and broad-spectrum antibiotic coverage as soon as the disease is recognized.
- Immediately consult a surgeon, as aggressive debridement is necessary in most cases. If appropriate care is unavailable, consider a rapid transfer to a facility with such services.

DISPOSITION

Surgical drainage with wide debridement and antibiotic therapy must be instituted rapidly because of the extremely aggressive nature of Fournier gangrene (7). Postoperative hyperbaric oxygen therapy has also been recommended and may promote wound healing (1,5,6,11).

All patients with scrotal cellulitis, deep abscess, or Fournier gangrene should be admitted to the hospital, and most will require surgery and critical care resources.

Patients should be transferred if surgical consultation or intensive care beds are not available.

Common Pitfalls

- Underestimating the severity of infection. With Fournier gangrene, a delay of several hours can make a significant difference in morbidity (1,4,7).
- Failure to rapidly institute fluid resuscitation, antibiotics, and surgical consultation.

CHAPTER 126 Urolithiasis

Stephen R. Hayden and Michael P. Wilson

Calculous disease (from the Latin *calculo&hibar;sus* or “pebble”) of the urinary tract affects people of all ages (1). As many as 2 million outpatient visits per year may be related to urinary calculi, termed *urolithiasis* or more commonly “stones.” As many as 6% to 12% of adults may experience a symptomatic kidney stone during their lifetime (2). This incidence is variable according to the geographic location, climate, and season. The southeastern United States has been called the “stone belt,” because it is a geographic area with an unusually high incidence of urinary calculi, especially during the summer (3). The incidence of calculous disease in Caucasians is reported to be approximately twice that in African Americans and Asians. The male-to-female ratio is approximately 2:1. The disease is relatively uncommon in patients younger than 15 years, with the highest incidence during the third and fourth decades of life. There are four basic types of urinary calculi: calcium salts, struvite, uric acid, and cystine (3). The underlying pathophysiology of stone formation in the urinary tract is complex, likely involving supersaturation of the involved salt. Stones that contain calcium salts are by far the most common type of stone encountered (Table 126.1). Struvite (ammonium magnesium phosphate) is the second most common type and is associated with infection by urea-splitting organisms such as *Proteus, Klebsiella, Staphylococcus* sp, and *Providencia.* The third type of stone, from uric acid, is less common in its pure form, occurring with an estimated frequency of 10%. The fourth type of stone, from cystine, is rare, representing $<1\%$ of all stone disease. Patients who form cystine stones have the autosomal

recessive genetic disorder cystinuria. The natural history of urinary calculi varies according to the size of the stone (Table 126.2) (4). Most stones 5 mm or smaller will pass spontaneously, with higher rates of passage for calculi located in the midureter or more distally. Vesical calculi occur predominantly in males. Most bladder calculi present during adult life and are secondary to bladder outlet obstruction or foreign bodies in the bladder, such as an indwelling catheter. Calcium oxalate is the most common constituent of bladder calculi in the United States, although the incidence of struvite and hydroxyapatite calculi in the bladder is higher than in the kidneys.

TABLE 126.1
Distribution of Various Stone Types (by Predominant Compound)[a]

Stone Type	Percentage (%)
Calcium oxalate	72
Infection stones (struvite and carbonate apatite)	16
Uric acid	6

[a]Adapted from Coll DM, Varanelli MJ, Smith RC. Relationship of spontaneous passage of ureteral calculi to stone size and location as revealed by unenhanced CT. *AJR Am J Roentgenol*. 2002;178:101–103.

CLINICAL PRESENTATION

Patients with urinary calculi often present writhing in pain, unable to find a comfortable position. Although pain is the principal reason for an emergency department (ED) visit, hematuria and symptoms of urinary tract infection are common complaints. Many patients also have a history of previous stones. Calculous disease is rare in children and, when encountered, may indicate a genetic or metabolic disorder. Symptoms compatible with both a kidney stone and a urinary tract infection may suggest a true urologic emergency—an obstructing stone associated with infection. The pain of renal calculi is acute in onset because of rapid distention of the renal pelvis and upper ureter. It is visceral in nature, with waxing and waning of symptoms. Typically, the pain is localized to the flank, but may be referred to the ipsilateral testis or labia because of similar embryonic origin of these structures. As the stone moves down the ureter, the pain may move from the flank to the ipsilateral lower quadrant of the abdomen. As the stone nears the bladder, symptoms of frequency and urgency may occur. Nausea and vomiting are common, being most intense at the peak of the colic episode. The pain of renal colic, in which patients are unable to find a comfortable position, is in contrast to patients with peritonitis, who typically lie still because movement aggravates their pain. Tachycardia, tachypnea, and hypertension may be present because of sympathetic stimulation from the pain. A fever implies a concomitant urinary tract infection. Costovertebral angle tenderness is often present, and auscultation of the abdomen may reveal diminished bowel sounds because ileus commonly accompanies renal calculi. Typical symptoms of bladder, or *vesical calculi,* include pain on voiding and hematuria. The pain, which may be dull or sharp, is often severe, with exercise or sudden movement, at the end of micturition. Hematuria often occurs at the end of voiding. Interruption of the urinary stream from impaction of the stone at the bladder neck may occur. Frequency, urgency, and dysuria are present in up to 50% of patients. Urinary tract infection is common, especially if an indwelling catheter is present.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with suspected urinary calculus is broad (Table 126.3). Urologic diseases that simulate urolithiasis may be divided according to anatomic site. Upper tract diseases include renal infarct and tumors. The upper ureter may be obstructed by blood clots or sloughed renal papillae; the latter are seen most commonly in patients with sickle cell disease, analgesic abuse, and diabetes mellitus. Ureteral obstruction may be secondary to prior urologic instrumentation, tuberculosis, ureteral strictures, surgery, intrinsic urothelial tumors, or extrinsic compression due to metastatic tumors or other masses. Important, nonurologic causes of flank pain include peritonitis, abdominal aortic aneurysm, appendicitis, diverticulitis, biliary colic, ovarian cyst, retroperitoneal lymphadenopathy from tumors (the most common of which is lymphoma), and retroperitoneal fibrosis. A Munchhausen-like syndrome featuring flank pain may be encountered in the ED. These patients are typically quite knowledgeable about urolithiasis. The hematuria often resolves when the urine is collected in the presence of a nurse or physician, and these patients typically require large doses of narcotics to alleviate pain. This group of patients poses a significant management problem for the physician, and the burden of proof is on the physician to rule out a true pathologic process.

TABLE 126.3
Diseases that Simulate Urolithiasis

Urologic Disease	Nonurologic Disease
Renal infarct	Appendicitis
Renal parenchymal tumors	Diverticulitis
Papillary necrosis	Biliary colic
Pyelonephritis	Intestinal obstruction
Hematoma	Abdominal aortic aneurysm
Ureteral stricture	Retroperitoneal adenopathy
Urinary retention	Tumor
	Ovarian cyst
	Endometriosis
	Musculoskeletal back pain

ED EVALUATION

It is important to be certain that an *obstructive* calculus does not coexist with urinary infection, because such patients are at significant risk for the development of urosepsis. The ED evaluation of patients with suspected renal stones should reflect these concerns. The most important initial laboratory test is the urinalysis. Most patients with urolithiasis have hematuria, but 10% to 15% do not. The degree of hematuria is not predictive of the severity of disease (5). A pH >7.5 in a fresh urine specimen suggests infection with urea-splitting organisms. Culture is helpful in such cases. Serum electrolyte levels are usually normal and it is not necessary to routinely test them. However, prolonged vomiting may lead to metabolic alkalosis. Serum creatinine levels are usually normal but can be elevated in cases of prolonged, high-grade obstruction. Hypercalcemia (calcium level >10.2 mg/dL) in a patient with nephrolithiasis may signal the presence of primary hyperparathyroidism. Leukocytosis is common because of demargination of white blood cells caused by the stress of renal colic and does not necessarily suggest infection. Radiologic studies are essential in establishing the diagnosis of urolithiasis. Approximately 90% of urinary calculi contain calcium, but many studies report that <50% are actually visualized on plain radiographs. An imaging study such as computed tomography (CT) scan is usually therefore necessary for the initial diagnosis of urolithiasis (6). The sensitivity and specificity of CT ranges from 96% to 100%, and the study is generally quite rapidly performed (7). CT demonstrates renal and ureteral calculi, including radiolucent calculi, and gives information regarding the presence or absence of hydronephrosis and the degree of obstruction (Fig. 126.1). Importantly, CT also provides important information about other retroperitoneal and intra-abdominal conditions in approximately 16% of cases (8). However, concern is growing about the cumulative radiation exposure of multiple CT scans, particularly in young people. In some cases, it is desirable to avoid both contrast and radiation (i.e., pregnancy). Ultrasound (US) is a viable alternative in this setting. US is approximately 16% sensitive for stones <7 mm, but perhaps as much as 75% sensitive

for stones ≤7 mm, and is highly sensitive for hydronephrosis (9). US may be most useful in patients with known calculous disease, as repeat CT scanning does not often change management in these patients (10).

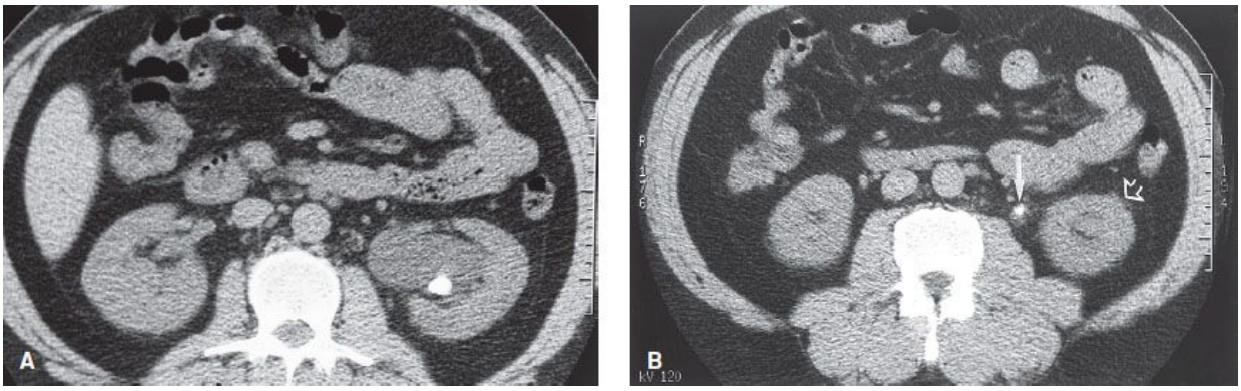

FIGURE 126.1 Noncontrast spiral computed tomography (CT). **A:** Large stone in the hydronephrotic left kidney. **B:** A 5-mm stone in the ureter, surrounded by soft tissue—the "soft-tissue rim" sign (*solid arrow*). Also note minimal left perinephric stranding near inferior pole of kidney (*open arrow*). (From West OC, Tamm EP, Kawashima A, et al. Nontraumatic emergencies. In: Harris JH Jr, ed. The Radiology of Emergency Medicine, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000:622, with permission.)

KEY TESTING

- Urinalysis and pregnancy test
- CT scan or US as discussed above

ED MANAGEMENT

The management goals in the ED are to make the proper diagnosis and provide relief of the pain. Analgesia should be provided simultaneously with diagnostic testing. Morphine and hydromorphone are common parenteral narcotics used in treating colic, and large, repeated doses may be necessary to relieve the initial pain. Anticholinergic or spasmolytic medications commonly used in Europe have not been found to be uniformly useful in the United States. The pain of ureteral colic is mediated by

prostaglandins released by the ureter in response to dilation. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin synthesis and decrease glomerular filtration. Ketorolac (Toradol) is the only parenteral NSAID available in the United States, and it has been shown to be as effective as opioids in relieving the pain of ureteral obstruction (11). Ketorolac is considered by many as the agent of choice for initial management of renal colic. Maximal pain relief using ketorolac has been shown to occur approximately 45 to 60 minutes after a parenteral dose. It is reasonable to treat patients with severe pain with an opioid analgesic given simultaneously with an initial dose of an NSAID such as ketorolac or ibuprofen. NSAIDs should be used with caution in patients with a history of gastrointestinal bleeding, renal insufficiency, or cardiovascular disease. Acute decreases in renal blood flow (35%) were noted after acute infusion of ketorolac in a unilateral ureteral obstruction dog model (12). Acute, transient renal failure occurred in six patients with cardiovascular disease when given ketorolac (13). Nausea and vomiting are common with ureteral colic and can be exacerbated by opioids. In such patients, administration of an antiemetic agent is appropriate.

IV fluid therapy has not been shown to reduce pain or facilitate stone passage in acute urolithiasis and is not necessary unless the patient is volume depleted. Stone-dissolving agents play a limited role in acute treatment, and the main options are either conservative or surgical (14).

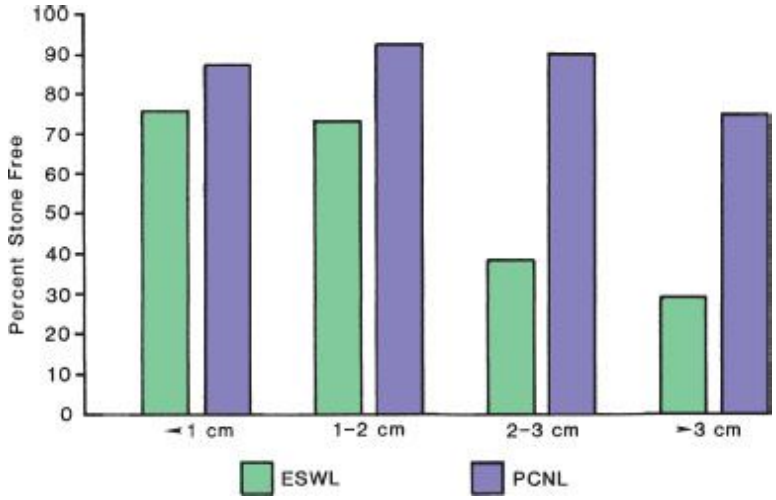
Recent evidence suggests that the selective α-blocker tamsulosin (Flomax), when added to standard pain control regimens, may increase the rate of successful stone passage within 1 month and reduce the time to successful stone passage by 2 to 6 days (15). The recommended dose of tamsulosin is 0.4 mg per os (PO) daily for 7 to 14 days or until stone passage occurs. Tamsulosin or other α-blockers are recommended over other types of medical expulsive therapy such as calcium channel blockers (16), but their efficacy remains disputed.

Infected stones can be associated with significant morbidity, especially in the setting of high-grade urinary obstruction (17). The common organisms in urine and blood cultures are *Escherichia coli,*

Proteus, and *Klebsiella* sp. Bacteremia is seen in 70%, and septic shock occurs in approximately 20%. Antimicrobial coverage, usually with fluoroquinolones, is directed at these organisms. Infection in the setting of high-grade obstructive uropathy requires emergent decompression. Given the risks of urosepsis, the American Urological Association further recommends that patients with urolithiasis and bacteriuria but without clinical signs of urinary tract infection should also be treated with appropriate antibiotics (16).

Urologic Interventions

The acute management of urinary tract stones is dependent on the presence of related complications, namely renal impairment or infection (acute obstruction alone is not a primary indication for intervention) (18). Emergency drainage can be achieved by placement of either a nephrostomy catheter or a retrograde stent. The choice between the two is often based on local experience and resources, but a nephrostomy may be preferable in the presence of significant sepsis and thick pus. Several technologic advancements have revolutionized the treatment of symptomatic urolithiasis in the past several decades (Table 126.4). The most important of these advancements has been the development of extracorporeal shock wave lithotripsy (ESWL). This technology has been proven effective in the management of 85% to 90% of cases that require intervention. Patients with large stones (i.e., >2 cm in diameter), cystine stones, and staghorn calculi are much less likely to become stone-free with ESWL monotherapy (eFig. 126.1). Ureteral calculi can also be managed effectively with ureteroscopy with or without stenting. This allows visualization of the entire ureter from the bladder to renal pelvis and removal of ureteral calculi under direct visualization. In general, upper ureteral calculi tend to be managed with ESWL or nephroscopy, whereas ureteroscopy is commonly used for distal ureteral stones (15,18). An important goal is to prevent further stone formation. Medical therapy based on stone analysis can dramatically reduce the incidence of recurrent stone formation (15). This evaluation may be initiated in the ED by checking serum electrolyte levels.



eFIGURE 126.1 Percentage of patients who are stone-free after extracorporeal shock wave lithotripsy (ESWL) and percutaneous nephrostolithotomy (PCNL), stratified by initial stone size. Most ureteral calculi are <2 cm in diameter.

2. Percutaneous nephrostolithotomy
3. Ureteroscopy
4. Extracorporeal shock wave lithotripsy
5. Observation

CRITICAL INTERVENTIONS

- Search for evidence of concomitant urine infection or bacteriuria.
- Provide adequate analgesia with a combination of opioids and NSAIDs.

DISPOSITION

Most patients with adequate control of symptoms and without signs of infection may be treated as outpatients with oral analgesics and antiemetics. Those with isolated pyuria, without other clinical signs of infection, may often be treated as outpatients. Pending the results of currently ongoing research, medical expulsive therapy with α-

blockers such as tamsulosin may be offered. Patients should be counseled on the side effects of medical expulsive therapy, including that this is an off-label use of these medications. They should be instructed to strain the urine and save any stones for analysis, and should be instructed to seek immediate medical for recurrent severe pain, persistent vomiting, or onset of fever. Outpatient urologic follow-up should be arranged within 2 weeks for all stones, and sooner for those with large stones.

The most common factor necessitating admission is severe, refractory pain. Persistent nausea and vomiting, obstruction with clinical signs of infection, renal stones >10 mm, and urinary extravasation on CT are other indications for admission (Table 126.5). Infection in the presence of high-grade obstruction from a stone is a urologic emergency that necessitates not only admission but also immediate urologic intervention. Drainage can be accomplished either by cystoscopy and passage of a ureteral catheter or by placement of a percutaneous nephrostomy tube. Antibiotics alone are not adequate therapy in these circumstances because the patient can otherwise experience continued bacteremic showering, progression to frank urosepsis, and rapid destruction of the involved kidney. Delay in drainage can lead to significant morbidity and death. Another factor influencing the disposition is the stone size. Calculi <5 mm usually pass spontaneously, whereas those >8 mm rarely do (14). Patients with high-grade obstruction are more likely to require intervention and admission. Patients with a solitary kidney or underlying intrinsic renal disease are more likely to experience a significant decrease in renal function with any degree of obstruction, so the threshold for admission of such patients is lower. Calculi that develop in patients with a renal transplant are usually managed in the inpatient setting to best preserve the graft.

TABLE 126.5

Indications for Admission
Obstruction with clinical signs of infection
Pain not controlled by oral analgesics
Persistent nausea and vomiting
Urinary extravasation
Hypercalcemic crisis
Relative Indications for Admission
High-grade obstruction
Solitary kidney
Intrinsic renal disease
Large obstructing stone
Long duration of symptoms
Inadequate social situation

Common Pitfalls

- The most common misdiagnosis in patients ultimately found to have abdominal aortic aneurysm is kidney stone. CT is helpful in making the correct diagnosis.
- Pain not responding to appropriate pain control measures is often associated with high-grade obstruction.
- Admission may be indicated for patients with systemic signs of urinary tract infection.
- Oral antibiotics are recommended for patients with bacteriuria, even in the absence of infection.

CHAPTER 127

Urinary Incontinence and Retention

Stephen J. Wolf

Micturition is a process that relies on the nervous, musculoskeletal, and genitourinary systems. Disruption of any of these systems can potentially lead to urinary dysfunction, resulting in incontinence or retention. The key aspect for an emergency physician in treating patients with incontinence or retention is ruling out emergent causes or complications of the urinary dysfunction (e.g., spinal cord compression or acute postobstructive nephropathy). Often times in doing this, the emergency physician is able to identify key contributing pathology. Once emergent issues are ruled out, most patients can be referred for an outpatient workup of their urinary complaints.

The physiology of micturition involves both conscious (somatic) and unconscious (autonomic) regulation. A cholinergic parasympathetic sacral reflex arc is fundamental in this process and involves the bladder wall, the detrusor muscle, and the vesicular sphincter. At low bladder pressures and distention, parasympathetic tone is low, leading to high urethral sphincter tone and low detrusor activity via the pudendal nerve. β-Adrenergic sympathetic stimulation from levels T10 to T12 also contributes to detrusor and bladder relaxation, while α-adrenergic innervation of the vesicular sphincter results in its resting tone. All of these mechanisms work to promote urine storage and are, in part, modulated by pontine urinary centers.

When bladder distention increases and voiding is desired, micturition is achieved by increasing parasympathetic tone and decreasing sympathetic tone. This, combined with subcortical stimulation of the pontine urinary center and somatic stimulation of the bladder, results in bladder wall contraction and sphincter relaxation. Because sympathetic fibers utilize α- and β-adrenergic receptors and the parasympathetic fibers utilize cholinergic receptors, they are vulnerable to pharmacologic manipulation. Thus, physical or pharmacologic disruption of these systems can result in urinary dysfunction.

CLINICAL PRESENTATION

Urinary incontinence is the involuntary loss of urine, often associated with social embarrassment, isolation, depression, and hygienic complications (1). It can be attributed to a sudden increase in intra-abdominal pressure (stress incontinence), involuntary bladder contractions (urge incontinence), a mixture of the two (mixed incontinence), overflow in the setting of urinary retention (overflow incontinence), complete disruption of the continence apparatus (true incontinence), or nonpathologic causes (functional incontinence) (1–6).

Urinary retention is the inability to void voluntarily, resulting in bladder distention. With this distention, symptoms of prostatism often develop, including frequency, urgency, hesitancy, dribbling, decrease in voiding stream, and a sense of incomplete emptying (1). This can further progress to acute or chronic postobstructive nephropathy. These symptoms may be exacerbated with the application of suprapubic pressure (the *Credé maneuver*). In the past, this maneuver has been used to initiate voiding in patients with retention; however, it is not recommended because of high complication rates and poor efficacy (7,8).

Although urinary retention is often considered a disorder of elderly men with enlarged prostates, it can affect men and women of all ages and even is seen in children. Often the retention is insidious in its onset, resulting from chronic progressive obstructive

or neurosensory causes (e.g., diabetes); however, acute presentations do occur, especially in the setting of urologic infections, certain medications, or neurologic disease.

DIFFERENTIAL DIAGNOSIS

Urinary Incontinence

Stress urinary incontinence (SUI) results when a rapid rise in intra-abdominal pressure is transmitted to the bladder, thereby causing a leakage of urine (3,4). It may result from sneezing, coughing, laughing, exercise, and so forth. Normally, the vesiculourethral anatomy is such that this transmitted abdominal pressure causes a narrowing of the posterior ureterovesical angle, making leakage of urine more difficult. However, this is not the case if there is hypermobility of the urethra or laxity in the intrinsic urethral sphincter. Nearly 85% of SUI occurs in women who have given birth, which can cause laxity of the anterior vaginal wall and pelvic floor, resulting in urethral hypermobility (5,9). Other risk factors include obesity and previous urinary incontinence surgery. Deficiency of the intrinsic urethral sphincter may also result from mechanical issues (trauma, surgery, and chronic bladder overdistention) or neurophysiologic issues (estrogen deficiency, diabetes, corticosteroid therapy, and radiation therapy). Finally, although the majority of SUI occurs in women, transurethral resection of the prostate (TURP) is a particular risk factor in men, whereas structural abnormalities should be considered as a cause for SUI in children.

Urge incontinence occurs when there is uninhibited involuntary contraction of the detrusor muscle and bladder wall (*detrusor instability*) (4). This is often called a "spastic bladder" or an "overactive bladder." Detrusor instability is the most common cause of urinary incontinence among the elderly, with a prevalence of 40% to 70% (2). Urinary frequency and urgency are common symptoms. Up to 90% of these cases are considered to be idiopathic. The remaining 10% result from bladder wall irritation/inflammation, urethral syndrome, or neurologic causes

(10). Bladder wall irritation and inflammation are usually caused by urinary infections. Treatment often results in resolution of the urge incontinence. Cystitis may also be caused by calculi, radiation, medications (cyclophosphamide, bacille Calmette–Guérin vaccine), or carcinoma in situ. *Interstitial cystitis* is a unique idiopathic, noninfectious cause of urge incontinence, with inflammation of the muscular layers of the bladder wall. It usually affects women in their third decade of life and results in progressive vesicular fibrosis, eventually leading to decreased bladder compliance and capacity.

Urethral syndrome may also lead to urge incontinence. It most commonly affects women and is a syndrome that consists of urgency, frequency, and dysuria. It is often clinically misdiagnosed as infectious cystitis, but urine cultures are negative and the urinary sediment is noninflammatory, showing squamous epithelial cells.

Neurologic causes of urge incontinence include, but are not limited to, stroke, multiple sclerosis, hydrocephalus, and suprasacral spinal cord lesions (acute cord compression or cauda equina syndrome). In these instances, the normal physiologic relations between the sacral detrusor-sphincter reflex arc and the pontine urinary centers can be disturbed, resulting in detrusor hyperreflexia as opposed to instability.

The differentiation between stress and urge incontinence is not always straightforward, and the clinical pictures overlap, yielding a *mixed incontinence* diagnosis. Fifty percent to 60% of patients presenting for evaluation of SUI also have an urgency component (5).

Overflow incontinence is a form of incontinence that occurs in the setting of obstructive urinary retention. Obstruction can result in constant dribbling, frequency, and an urge incontinence pattern with detrusor instability.

True incontinence resulting from complete disruption of the continence apparatus or fistula formation, functionally produces a “drain-spout urethra.” This can be due to trauma, surgeries (TURP or previous urethral surgeries), vaginal or cesarean deliveries, malignant erosion or ischemic disease from operative, chemical, or

radiation factors. Congenital abnormalities are also a cause for true incontinence in children.

Finally, nonpathologic or *functional incontinence* should be considered in the differential diagnosis. Patients with functional incontinence have normal anatomy and function, but the incontinence is due to psychological factors or physical limitations in getting to the bathroom. Such constraints could include altered mental status, ethanol intoxication, isolated urinary tract infection, medication use, depression, excessive urine production, or restricted mobility. Other nonpathologic causes of incontinence include enuresis in the pediatric population and incontinence for other psychologic gains. The latter is associated with a sparing of nighttime incontinence while the patient sleeps.

Medications often contribute to urinary incontinence by causing detrusor instability, decreased sphincter tone, functional incontinence, or urinary retention resulting in overflow incontinence. Table 127.1 lists classes of medications that may contribute to urinary incontinence. A helpful mnemonic for transient causes of urinary incontinence is DIAPPERS (Table 127.2).

TABLE 127.1
Medications Associated with Voiding Dysfunction[a]

Drug Classes that can Contribute to Urinary Incontinence
Alcohol
Caffeine (11)
Diuretics
Sedative–hypnotics
Sympatholytics
Drug Classes that can Contribute to Urinary Retention[b,c]
α-Adrenergic agents
Antiarrhythmic
Anticholinergics
Antidepressants
Antihistamines
Antiparkinsonian agents
Antipsychotics
Antispasmodics
β-Adrenergic agents
Calcium channel blockers
Opioids

[a]Prescription and over-the-counter.
[b]Medications that alter sensorium and can also contribute to urinary incontinence.
[c]Medications that contribute to urinary retention and can also lead to overflow urinary incontinence.

*E*xcessive urine output
*R*estricted mobility
*S*tool impaction

Urinary Retention

Urinary retention is most often the result of obstruction; however, it can also result from neuropathologic disease, pharmacologic side

effects, or psychogenic causes (1). Special congenital considerations also arise when considering the etiology of urinary retention in the pediatric population (Table 127.3). Urinary retention needs to be delineated from anuria and oliguria, which is a lack or decrease of urine production from the kidneys and not an issue of voiding dysfunction.

TABLE 127.3
Obstructive Causes of Urinary Retention

Functional

- Benign prostate hypertrophy
- Bladder calculi
- Bladder neck stenosis
- Blood clot
- Cancer (e.g., prostate, bladder, urethral, cervical, and colon)
- Cystocele
- Iatrogenic (e.g., previous anti-incontinence procedures)
- Meatal stenosis
- Phimosis–paraphimosis
- Pregnant uterus
- Prolapsed uterus
- Rectocele
- Trauma
- Urethral obstruction (e.g., calculi, inflammation, trauma, and tumor)
- Urethral diverticulum
- Urethra stricture (male predominance)

Infections/Inflammatory

- Cystitis
- Genital herpes
- Periurethral abscesses
- Prostatitis
- Sexually transmitted diseases
- Tuberculosis
- Urethritis
- Vesicoureteral reflux (female predominance)

Additional Pediatric Causes

- Benign hyperplasia of the prostatic utricle
- Congenital obstructed duplications of the urinary system
- Constipation
- Cystic enlargement of the posterior urethra
- Foreign bodies
- Hydrocolpos (from an imperforated hymen)
- Urethral valves (posterior or anterior)
- Ureterocele
- Ureteropelvic junction narrowing
- Ureterovesical junction narrowing
- Vaginal atresia/vaginal stenosis

Obstructive urinary retention can be a result of multiple etiologies and occurs much more frequently in men (see Table 127.3). Benign prostatic hypertrophy is the most common etiology, usually occurring in the sixth decade of life. Prostate cancer is a less common cause of obstruction and is associated with a marked elevation of prostate-specific antigen level (1). Fibromuscular contracture of the bladder outlet can occur in the younger male. At the level of the bladder outflow tract, calculi, blood clots, tumor, or polyps can all cause obstruction. At the level of the urethra, obstruction can be secondary to inflammation or stricture. Inflammatory causes include urethritis, prostatitis, tuberculosis, echinococcosis, and herpes simplex. Strictures can result from gonococcal urethritis, trauma, surgery, or radiation but tend not to be caused by nongonococcal urethritis (1). A higher incidence of psychogenic urinary retention tends to be found in women.

Neuropathologic causes of urinary retention deserve special attention (Table 127.4). Neurologic lesions (e.g., trauma, mass lesions, and infections) at the level of the sacral nuclei can disrupt the spinal reflex arc, thereby causing a flaccid paralysis of the bladder and an inability to void. *Suprasacral lesions* of the spinal cord or central nervous system may initially result in spinal shock–type physiology with urinary retention, but usually progress to overflow and urge incontinence with detrusor hyperreflexia, owing to the lack of upper-motor neuron control. However, a complication of suprasacral injuries can be *detrusor-sphincter dyssynergy,* in which there is external sphincter spasm during bladder contraction, resulting in urinary retention.

TABLE 127.4
Neuropathologic Causes of Urinary Retention

Suprasacral Pathology Resulting in Detrusor-Sphincter Dyssynergy

- Encephalitis
- Hydrocephalus
- Meningitis
- Parkinson disease
- Shy–Drager syndrome (12)
- Spinal cord trauma
- Spinal cord tumors (benign, primary, malignant)
- Spinal/paraspinal infections (abscesses, osteomyelitis, discitis)
- Stroke
- Tabes dorsalis

Sacral Pathology Resulting in the Disruption of the Reflex Arc

- Inflammatory polyradiculopathy
- Sacral spinal/parasacral infections
- Sacral dysgenesis
- Sacral trauma

Supra Sacral or Sacral Pathology Resulting in an Impaired Spinal Reflex Arc

- Diabetes mellitus
- Landry–Guillain–Barré syndrome (13)
- Multiple sclerosis (14)
- Pernicious anemia
- Poliomyelitis
- Syringomyelia
- Transverse myelitis
- Isolated bladder atony and urinary retention

Finally, various medications, both prescription and over-the-counter, can precipitate urinary retention (see Table 127.1). Anticholinergic medications inhibit parasympathetic tone and promote urinary retention. Likewise, α- and β-adrenergic medications cause bladder wall relaxation and an increase in urethral sphincter resting tone. This risk is even greater in the setting of other risk factors, for example, a male patient with benign prostatic hypertrophy taking an over-the-counter cold medicine with diphenhydramine.

ED EVALUATION

Urinary Incontinence

The emergency department (ED) evaluation of urinary incontinence should be focused on identifying acute emergent or correctable causes. Most emergent causes are neurologic, resulting in detrusor hyperreflexia, whereas most correctable causes are infectious, overflow, or medication related. The evaluation should focus on a thorough history covering past medical, surgical, psychosocial, and medication histories. Any of these elements may yield clues to the etiology of incontinence. The physical examination should include a thorough neurologic examination, including mental status, gait, deep-tendon reflexes, saddle sensation of the perineum, rectal tone, and the bulbocavernosus reflex. An absent bulbocavernosus reflex in male patients is almost always associated with a neurologic lesion. In women, it can be absent up to 30% of the time (1).

SUI is often implied by the history and is accompanied by a normal physical examination. If needed, a provocation test for SUI can be performed by instilling 200 to 300 mL of sterile saline into the bladder after the measurement of a postvoid residual (PVR) (5). The patient can then be asked to sneeze, cough, or strain. Isolated leakage suggests SUI. Furthermore, if the *Marshall test,* digital urethral support during a provocation test, prevents the incontinence, the diagnosis is confirmed. Leakage with an inability to stop further urine flow during a provocation test suggests urge incontinence with detrusor instability. Urge incontinence may require investigation into associated signs and symptoms (e.g., back pain) for inflammatory etiologies and/or neurologic etiologies. Associated back pain or an abnormal neurologic examination warrants evaluation for overflow incontinence associated with an obstructive urinary retention.

Urinalysis and urine cultures should also be obtained. They may assist in the diagnosis of infection and noninfectious inflammatory causes.

Emergent urology consultation is not usually necessary, and extensive urologic evaluation is reserved for the outpatient setting. When acute neurologic causes of incontinence are suspected,

imaging studies, neurologic, or neurosurgical consultation should be obtained as needed.

Urinary Retention

Evaluation of acute or chronic urinary retention in the ED should be directed at identifying the cause, when possible, and evaluating for the sequela of renal parenchymal damage. Neurologic causes must be carefully excluded. Special attention should be paid to the review of the patient's medication history, the rectal examination, and a thorough neurologic examination. These can provide significant information as to the potential emergent etiologies of the urinary retention. It should be noted that a normal prostate on examination does not exclude prostatic cause from the differential diagnosis.

Two tests are particularly helpful. A PVR of more than 100 mL suggests retention. A bedside ultrasound can document bladder distention suggestive of outlet or urethral obstruction. This may be especially useful if symptoms persist in the setting of perceived adequate drainage.

Laboratory evaluation of patients found to have urinary retention should include a urinalysis with culture, blood urea nitrogen (BUN), and serum creatinine. The urinalysis can provide clues to infectious etiologies, calculi, or tumors, whereas the urine culture is necessary for detecting subclinical infections. Postobstructive nephropathy is often characterized by an elevated BUN/creatinine (Cr) ratio (i.e., >10). If new or previously undiagnosed renal insufficiency is present, a more complete workup with electrolytes and a renal ultrasound looking for hydronephrosis, hydroureter, or renal parenchymal damage is indicated.

KEY TESTING

Urinary Incontinence

- Blood Sugar, Urinalysis and culture
- Neurologic imaging (when indicated)

Urinary Retention

- Postvoid residual or postvoid volumetric bladder scan

- BUN and creatinine
- Urinalysis and culture
- Renal ultrasound (when indicated)
- Neurologic imaging (when indicated)

ED MANAGEMENT

Urinary Incontinence

Emergent neurologic causes should be addressed as dictated by the suspected etiology, such as ordering emergent magnetic resonance imaging (MRI) in cases of suspected spinal cord compression. Transient causes (see Table 127.2) should also be addressed (e.g., administering antibiotics for infectious cystitis or withholding offending medications when possible).

Further management of stress, urge, true, functional, and nonpathologic incontinence falls into the realm of outpatient urologic consultation. The management of SUI and true incontinence is often surgical, with repositioning of vesicourethral angle (e.g., bladder neck suspensions and pubovaginal slings). Alternatives for SUI include Kegel exercises, weight reduction, estrogen replacement, electrostimulation methods, and α-agonists (pseudoephedrine, phenylpropanolamine) for increasing bladder neck and urethral tone (2). Periurethral collagen injection therapy and urethral occlusion devices have also been used with moderate success for treating SUI (3). Anticholinergic medications (propantheline, hyoscyamine) increase the tolerable bladder volume and decrease involuntary bladder contractions (15). Tricyclic antidepressants (doxepin, imipramine) can also be used to increase bladder tone gives their central and peripheral anticholinergic effect. Oxybutynin and dicyclomine inhibit involuntary bladder contraction through anticholinergic effects and cause smooth muscle relaxation in the bladder wall. Tolterodine has similar effect as oxybutynin via antimuscarinic activity.

Urinary Retention

Initial management of urinary retention should focus on identifying serious neurologic causes and obtaining symptom relief through bladder decompression. Decompression can be accomplished with a well-lubricated 16 to 18Fr catheter and should be done in a timely manner. If this is unsuccessful, attempts can be made with a coudé catheter. Its angulated tip can facilitate catheter passage beyond the median lobe of the prostate. If a urethral catheter cannot be placed, temporary relief may be provided by placing a suprapubic catheter. This requires a palpable bladder and the absence of a history of prior suprapubic surgery. If there is doubt about bladder distention (as in the obese patient), ultrasound confirmation is advised. For percutaneous drainage techniques, a simple midline puncture is made one fingerbreadth above the symphysis pubis, with the trocar or needle directed slightly caudally and then advanced until urine is returned. The catheter or tubing is then advanced, the needle is withdrawn, and the drainage catheter is secured in position.

Traditionally, a single straight catheterization (in and out) of patients with urinary retention has not been recommended, as recurrence of symptoms is likely, and the risk of infection is high. More recently trials without catheter (TWOC) in men with prostatic hypertrophy using concomitant α-adrenergic blockade following initially catheter decompression have shown some success (48% to 62%), particularly in younger patients with low PVR volumes (10).

Bladder mucosal hemorrhage and postobstructive diuresis are two complications of bladder decompression, particularly in the patient with chronic urinary retention. Bladder mucosal hemorrhage is thought to be the result of sudden expansion of bladder wall veins after decompression (1). In the past, clamping of the catheter after a certain amount of drainage was recommended in an attempt to avoid this complication. However, it has been shown that the hydrostatic pressure in the bladder begins to fall immediately with catheter placement and falls markedly within the first 100 mL of urine drained. Therefore, clamping of the catheter does not affect the risk of mucosal hemorrhage and is not indicated (1,17).

Postobstructive diuresis may occur after the decompression of obstructive urinary retention at a rate up to or >1 L/hr. However, it

is believed that this diuresis is an appropriate correction of volume overload. Therefore, milliliter-for-milliliter replacement of this diuresed fluid is not indicated. What is indicated is replacement of the concomitant electrolyte loss that accompanies the diuresis. This can often be done through administering a maintenance rate of one-half isotonic saline during the diuresis (18).

CRITICAL INTERVENTIONS

- Exclude serious neurologic disease (e.g., spinal cord compression) as the cause of acute urinary dysfunction.
- Place a bladder catheter immediately to relieve the discomfort of bladder distention in patients with acute urinary retention.

DISPOSITION

Patients with an obstructive uropathy usually require continuous urinary drainage. The patient in otherwise good health with no ancillary requirements for hospital care may be discharged from the emergency department with Foley catheter drainage collected into a leg bag. Follow-up should be arranged prior to discharge, and there should be a thorough discussion with the patient about when to seek further medical attention. Urinary retention related to drugs or medication requires referral to the prescribing physician for recommended adjustment or substitution therapy.

Patients with an emergent neurologic cause of urinary incontinence or retention should be admitted or transferred if appropriate specialty consultation is not available.

Common Pitfalls

- Failure to diagnose a true neurologic emergency such as cord compression or cauda equina syndrome in the patient with urinary retention or incontinence.
- Failure to inquire about over-the-counter medication use.
- Overly aggressive attempts at catheter insertion, resulting in urethral injury.

- Failure to detect associated infection or postobstructive nephropathy in the elderly patient with urinary retention.
- Failure to consider multiple sclerosis and diabetes in a woman with urinary retention.

CHAPTER 128 Genitourinary Stents and Catheters

Jonathan E. Davis

URETHRAL CATHETERS

The need to place urinary catheters is common in the emergency department (ED). The reasons for placement vary widely and include the relief of urinary retention, monitoring urinary output for resuscitation efforts, treatment of gross hematuria, and obtaining a urine specimen. Urethral catheter placement is usually a routine and uncomplicated procedure but can sometimes be challenging. As with any other procedure, there are accompanying risks and complications. Emergency physicians should be able to utilize different types of catheters, be able to overcome the common difficulties encountered placing them, and be aware of the acute and chronic complications of urinary catheters.

Urinary catheter placement in the male patient may be complicated by several factors related to the length and path of the urethra. Common pathologic conditions may also make urinary catheter placement difficult (eTable 128.1). Meatal stenosis, either from prior infections, congenital malformation, or previous trauma can be diagnosed when the meatus of the penis is fibrotic and nondistensible. A dilation procedure performed by a urologist may be necessary for catheter placement to be successful. Hypospadias is a congenital condition in which the true urethral lumen is on the ventral aspect of the penis, making catheterization difficult. In a patient with known hypospadias, the glans penis should be inspected to identify a true urethral meatus, as there is often a blind-ended

lumen on the glans penis. The conscious patient should be able to state which lumen is functional. Once the lumen is identified, catheterization may proceed in the standard fashion.

eTABLE 128.1
Approach to Difficulties in Male Catheterization

Condition	Issue	Workaround Strategy
Phimosis	Inability to identify the urethral meatus because of a tight phimotic opening	Dilate the phimotic opening sufficiently to identify the urethral meatus and blindly pass the catheter Dorsal slit of the foreskin to expose the glans and urethral meatus in extreme cases
Foreskin edema	Edema may obscure glans penis and urethral meatus	Attempt to identify cause of edema; exclude paraphimosis or foreign body strangulation Manually compress the swollen foreskin by hand or between opposing cold packs If unsuccessful, snugly wrap the distal penis in a compressive dressing for 10 min
Meatal stenosis	Urethral meatus may be either congenitally or secondarily narrowed by scarring	Trial of smaller caliber catheter If larger caliber catheter necessary, meatal dilation or meatotomy might be necessary under the direction of a urologist
Urethral stricture	May develop as a result of trauma, infection (especially STIs), lower urinary tract instrumentation, or long-term indwelling catheter drainage	Trial with coudé catheter However, manual force should not be used to negotiate or to dilate urethral strictures—may lead to false passages, bleeding, and increased scarring Consideration of urethral dilation using filiforms and followers under the direction of a urologist
External urethral sphincter spasm	Voluntary or involuntary contraction of the urogenital diaphragm (external sphincter), produces spurious urethral resistance with catheter passage of about 16 cm from the urethral meatus	Encourage patient to lay supine and take slow, deep breaths, consciously trying to relax the perineum and rectum Plantar flexion of the toes and ankles may also aid relaxation of the pelvic floor Gentle but steady pressure exerted on the syringe or the catheter along with steps above may aid passage External sphincter is composed of striated muscle that fatigues within a few minutes If continued resistance, assume an anatomic abnormality and consider RUG prior to further instrumentation
High bladder neck	Enlarged intravesical portion of the prostate with a secondary high-riding bladder neck Typically resistance after the catheter has been passed 16–20 cm into the urethra	Slow instillation or injection of 20–30 mL of sterile lubricating jelly If unsuccessful, consider trial with coudé catheter; may be enhanced by digital compression of the prostate by digital rectal examination
Pelvic trauma, straddle injury	Partial or complete urethral injury might occur Injudicious catheterization has the potential for conversion of a partial injury (may heal with little or no scarring) to a complete urethral injury (often requires surgical repair and usually results in some degree of postoperative morbidity) Blood at the urethral meatus; a "high-riding" or abnormal-feeling prostate on rectal examination; and penile, scrotal, or perineal ecchymoses might be evidence of potential urethral or bladder injury, but have poor sensitivity	Consider precatheterization RUG in suspect cases Maintain a low threshold for urologic consultation Suprapubic catheter placement may be necessary in certain cases

RUG, retrograde urethrogram; STIs, sexually transmitted infections.

The male urethra is divided into the anterior (penile, bulbous) and posterior (membranous, prostatic) portions (Fig. 128.1). The penile and bulbar urethras are the most common sites of urethral strictures. Strictures are usually noticed when the catheter cannot be advanced more than halfway into the bladder, and the procedure is often accompanied by significant discomfort. There should not be attempts to force the catheter through a stricture. This force may create false

passages in the urethra, which can lead to urethral diverticuli, incontinence, infection, and fistula formation. If this situation is encountered, further attempts to place the catheter should be discontinued until a urology consult is obtained. The stricture may require a dilatation procedure or urethroplasty.

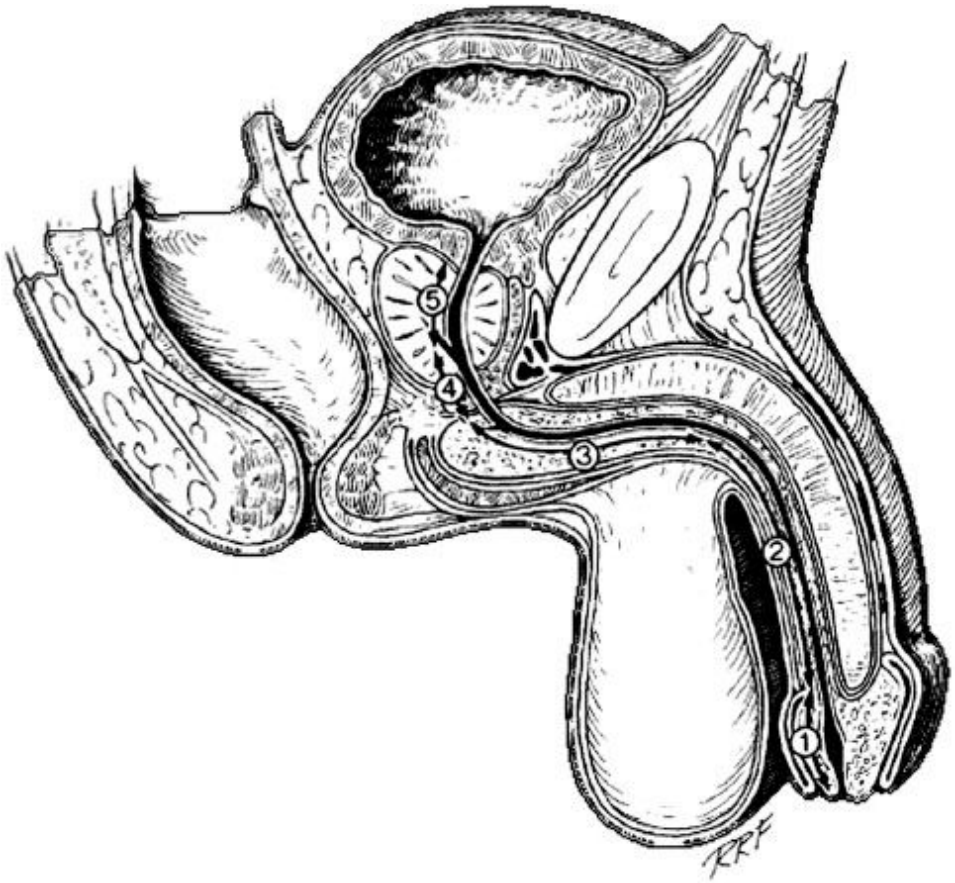

FIGURE 128.1 Anatomy of the male urethra. (1) Fossa navicularis, (2) pendulous urethra, (3) bulbous urethra, (4) membranous urethra, and (5) prostatic urethra. (From Jordan GH, Schellhammer PF. Urethral surgery and stricture disease. In: Droller M, ed. *Surgical Management of Urologic Disease.* St. Louis, MO: Mosby Year Book; 1992:394.)

The site for the most common problems for placement of male urinary catheters is the prostatic urethra, where the lobes of the prostate create a narrowed lumen. The incidence of benign prostatic hypertrophy (BPH) increases dramatically with advancing age, and

the vast majority of men older than 70 years have the anatomical changes, signs, and symptoms of BPH. There are a few basic techniques that can help in passing the tip of the catheter around an enlarged prostate. The use of a coudé catheter is often helpful. This catheter has a firm, upturned end which slips over the enlarged gland (1). Other techniques include placing a finger in the rectum and applying gentle pressure to the prostate as the catheter is passed, or injecting a water-soluble lubricant retrograde into the urethra to decrease friction. Patients who have undergone a radical or simple prostatectomy commonly have bladder neck contractures, and coudé catheters are similarly helpful in these patients. In instances when the ED placement of a catheter has been unsuccessful, urology consultation may be necessary.

Although the vast majority of difficult catheterizations occur in men, occasional difficulties arise in the catheterization of women. Women have short, straight urethras, which are easy to traverse with a standard urethral catheter. At times, however, identifying the urethral meatus can be problematic. Obese women may have redundant labial tissues, which can make visualization of the meatus difficult. Placing the patient in the frog-leg position, using adequate lighting, and having an assistant retract redundant tissue will often aid in the location of the urethral meatus and subsequent placement of the catheter.

Occasionally, prolapse of the pelvic organs (cystocele, enterocele, rectocele, or uterocele) can obscure the view of the female meatus. Simply applying gentle pressure to the offending organ should assist in bringing the meatus into view. Some women have a partially prolapsed urethra called a caruncle, which can distort the normal anatomy. A standard urethral catheter can usually be placed around the caruncle without difficulty.

Complications from the placement of urinary catheters occur uncommonly. If too much pressure is applied to a urethral catheter that is being impeded by a stricture or large prostate, a false passage can be created. This is a result of undermining the urethral mucosa; the consequences may include significant hematuria, stricture formation, and infection. In certain situations involving pelvic

trauma, urethral integrity should be assured via a retrograde urethrogram (RUG) prior to the placement of a urinary catheter (Fig. 128.2).

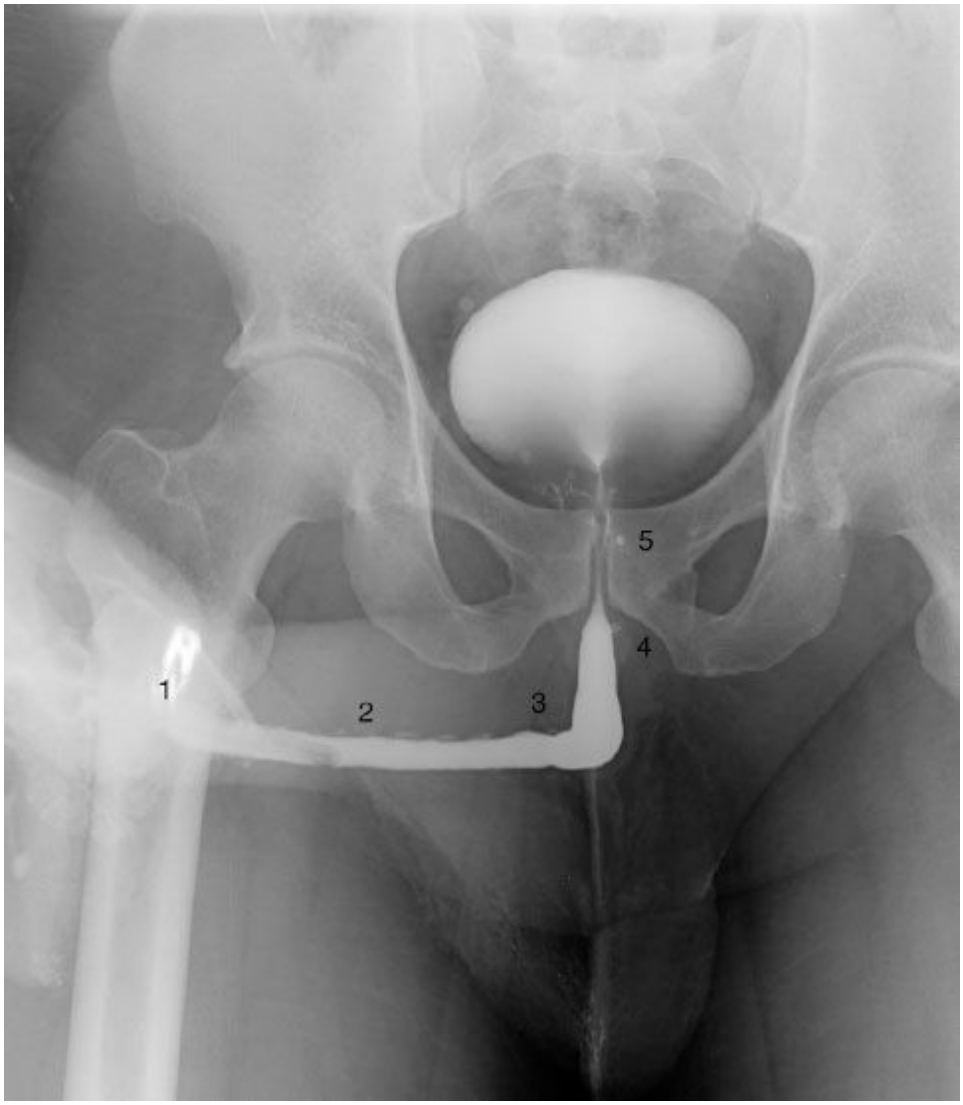

FIGURE 128.2 Anatomy of the male urethra, normal retrograde urethrogram. (1) Fossa navicularis, (2) pendulous urethra, (3) bulbous urethra, (4) membranous urethra, and (5) prosthatic urethra. (Courtesy of Michael Antonis, DO, RDMS.)

Occasionally a urethral catheter cannot be removed from a patient because the balloon will not deflate. The easiest maneuver is to cut the valve off the end of the catheter, which may facilitate removal. If this technique fails to relieve the obstruction, a guidewire can be

introduced into the balloon lumen of the catheter to attempt to relieve a balloon port obstruction preventing egress of balloon contents. If this method fails and the catheter needs to be removed emergently, a urologist may have to perform invasive maneuvers to better facilitate catheter removal.

A catheter may be forcibly pulled out of the bladder in patients with altered sensorium or other issues. Replacing the catheter is usually not difficult, but consideration should be given to any resulting injuries. Repeatedly pulling out a urinary catheter puts the patient at risk for developing incontinence secondary to external sphincter damage, and may also lead to hematuria with significant blood loss. If a urethral catheter that has been removed traumatically cannot be replaced easily, urology consultation should be obtained, and performance of a RUG should be considered.

Urinary tract infection is a complication of a long-term urethral catheter. The duration of catheterization is the most important risk factor for the development of catheter associated bacteriuria (2). The incidence of bacteriuria with indwelling catheterization is 3% to 8% per day. The rate might be considerably higher in hospitalized, elderly, debilitated, or postpartum patients. By 1 month, nearly all patients with an indwelling catheter will have bacteriuria. Urinary catheterization is the leading cause of nosocomial infection (2). Other less frequent complications of long-term indwelling urethral catheterization include bladder stones, recurring bladder spasm, periurethral abscesses, urethral stricture formation, bladder perforation (3), and urethral erosion (4).

When a catheterized patient presents with a urinary tract infection, the catheter should be changed. Patients with long-term need for catheterization should have them changed monthly. Antibiotic treatment is usually not indicated for asymptomatic patients, and may in fact select for antibacterial resistance. Many studies have documented the overuse of urethral catheters, and the best strategy for preventing catheter-related infections is the more judicious use (5).

Other problems from long-term indwelling catheters include local infections (epididymitis, balanitis, and prostatitis), erosive

hypospadias, and bladder stone formation (6). In general, urethral catheters are not the treatment of choice for debilitated or incontinent patients, and their indications should be carefully considered. Other options include intermittent catheterization, condom catheters, and suprapubic catheters.

THREE-WAY IRRIGATION CATHETERS

Placement of a three-way irrigation catheter may be required in ED patients complaining of gross hematuria and exhibiting symptoms of bladder obstruction. Gross hematuria is often complicated by obstruction secondary to the formation of blood clots. Significant bleeding should be treated aggressively with three-way catheter placement and bladder irrigation to maintain patency of the urethra and to accurately monitor the amount of bleeding. If gross hematuria persists or copious blood clots are encountered, continuous bladder irrigation can be therapeutic.

A three-way irrigating catheter is needed in patients who require continuous bladder irrigation. Three-way catheters have three ports, one providing standard access to urinary drainage, a second to instill irrigating solution, and a third to control the inflation of the balloon. Sterile saline or water may be infused passively through the irrigation port using a reservoir (Kelly) bag placed above the level of the bladder. There are several types of three-way catheters, ranging from a soft plastic coudé type to others with large holes at the distal end to facilitate the passage of large clots. When there is significant bleeding and clot formation, the three-way catheter with the largest tolerated diameter should be used.

SUPRAPUBIC CATHETERS

Suprapubic catheters are placed in patients for a variety of reasons revolving around a need for alternative bladder drainage. Suprapubic catheters that have been in place for longer than a month form a mature fistulous tract and therefore can be removed and changed without fear of losing tract patency. Changing the catheter over a guidewire facilitates this procedure. Before replacing a suprapubic

catheter, the bladder should be filled with saline or water to facilitate the correct placement of the new catheter into the bladder.

Suprapubic catheters may also become obstructed with mucous or debris. The catheter should be flushed to attempt to relieve the obstruction, which is similar to the procedure used with a standard urinary catheter. Suprapubic catheters should be replaced every 4 to 6 weeks or when they are suspected to be the nidus of an infection.

Occasionally there is a need to emergently place a suprapubic catheter in the setting of urinary retention when standard catheterization has failed, or in the setting of a traumatic urethral disruption. This should be performed by a consulting urologist when one is available, though the procedure is straightforward. Several techniques are described, the most common involving a percutaneous Seldinger technique, threading the catheter over a guidewire placed into the bladder via a suprapubic needle puncture. Patients who are significantly obese, have had prior abdominal or genitourinary surgery, or have had multiple prior suprapubic catheters are suboptimal candidates for percutaneous suprapubic tubes and usually require an open procedure in a more controlled operative setting to reduce the risk of complications.

URETERAL STENTS

The placement of ureteral stents is a common practice in urology to facilitate adequate urine flow through the ureter. The most common reason is for stone disease. A ureteral stent may be placed after a large kidney stone is treated. The most common stents are double-J stents that can be identified on plain films by the curls that are in both the bladder and the renal pelvis. Emergency physicians should be aware of their indications, complications, and side effects.

Stents are placed to allow the unimpeded passage of urine and to aid in the passage of stones into the bladder. Patients who have signs and symptoms of infected urine and also have signs of urinary obstruction (e.g., by stones or strictures) often have stents placed emergently to allow adequate drainage of urine and to prevent septic complications (see also nephrostomy tubes below).

Pain is the most common complication associated with urethral stents. The pain usually results from irritation of the mucosa of the renal pelvis or the bladder. Patients commonly complain of flank pain, dysuria, frequency, gross hematuria, and urgency. The symptoms usually abate in time but may require the use of narcotic pain medications. Symptoms may also be alleviated by oral anticholinergic agents, which may be started in consultation with a urologist. Other complications include infection, migration, obstruction, and encrustation. Bacterial colonization of ureteral stents is common. Patients with a urinary stent in place who exhibit signs or symptoms of urinary infection should be promptly treated with antibiotics, including adequate coverage for *Pseudomonas* species (7). Urology consultation is prudent in this situation.

Large obstructing ureteral calculi (e.g., greater than 10 mm in diameter) may impede the retrograde passage of a ureteral stent. Occasionally, a patient's anatomy does not allow perfect alignment of the ureteral stent in either the bladder or the renal pelvis, leading to stent migration. The stent can move proximally in the ureter or distally toward the bladder and often fails to function correctly. A one-view abdominal radiography (kidneys, ureters, and bladder [KUB]) is helpful in assessing stent location (Fig. 128.3).

FIGURE 128.3 A kidneys, ureter, and bladder view showing a stent in proper placement.

Stent encrustation (stone formation around a stent) and obstruction may occur when ureteral stents are not removed or changed for long periods of time. Patients can develop hydronephrosis or renal failure as a result. Urgent consultation for stent removal or replacement is often necessary.

NEPHROSTOMY TUBES

The primary urgent indication for percutaneous nephrostomy (PCN) catheter placement is to relieve an obstructed, infected renal collecting system (pyonephrosis). Pyonephrosis represents infection (pus) that is under pressure (obstructed collecting system). Pyonephrosis is associated with significant morbidity and mortality if not treated swiftly and aggressively. Relief of obstruction remains the cornerstone of treatment, with appropriate broad-spectrum intravenous antimicrobials playing an important adjunctive role.

Retrograde ureteral stents and PCN catheters have been demonstrated to be equally effective in relieving obstruction, with similar complication rates (8). The advantages of PCN catheters include: wide variety of available catheter sizes, ability to irrigate the catheter to avoid or alleviate clogging, direct measurement of urinary output from the affected kidney, and minimizing ureteral manipulation as to decrease the risk of precipitating sepsis or ureteral rupture. In addition, the procedure can typically be performed under local anesthesia with procedural sedation. Depending on institutional capabilities and local protocol, the procedure can be performed by an interventional radiologist. Advantages of cystoscopic ureteral stenting over PCN include decreased bleeding risk by avoiding puncture of the highly vascular renal capsule, lack of an external catheter exiting the flank, and often less postprocedural patient discomfort.

Emergent PCN is also utilized in the treatment of obstructive uropathy from a variety of causes associated with acute renal failure. Another general indication for PCN catheter placement is access to the renal collecting system for diagnostic or therapeutic procedures. PCN catheter placement may also be utilized as a secondary procedure if initial ureteral stent placement is unsuccessful, or fails to alleviate signs or symptoms of pyonephrosis. Major complications of PCN include sepsis, hemorrhage, vascular injury, bowl injury, or pleural complications. Complications occur in 2% to 6% of procedures, and have a higher frequency when PCN is performed after-hours likely owing to the overall higher risk profile of patients necessitating emergency intervention (Fig. 128.1) (9).

The decision regarding cystoscopy with ureteral stent versus PCN catheter placement for the treatment of pyonephrosis is multifactorial, and typically guided by a urologist in conjunction with an interventional radiologist if necessary. In general, however, emergent PCN catheter decompression is the treatment of choice in septic or otherwise unstable patients given anesthetic risks. In less extreme circumstances, a trial of cystoscopic ureteral stent placement is typically advocated as the first line in treatment.

URINARY CONDUITS

Bowel is sometimes used to serve as a surgically created conduit for urine; for example, this may be done after radical cystectomy for invasive bladder cancer. The most common form of urinary conduit is an ileal conduit formed by a small piece of ileum that has been removed and attached to the ureters. The distal end is then made into a stoma at the abdominal wall, and the urine is collected in an external urostomy bag. Other procedures include formation of a neobladder that is orthotopically placed, allowing the patient to void in the normal fashion. Another option is the formation of a stoma that may be catheterized through the umbilicus using a straight catheter.

As with any large abdominal and pelvic operation with bowel manipulation, patients may later develop a small bowel obstruction. Hernias can develop around the stoma (parastomal) or at the surgical site (incisional). Because the ureter is sutured to the bowel, a stricture can develop at the anastomosis, potentially causing hydronephrosis, insidious renal failure, pyelonephritis, or urosepsis. Because the ureteroileal anastomosis allows the free reflux of urine, pyelonephritis is common in these patients. Because conduits are chronically colonized with fecal flora, positive urine cultures should typically be treated only if the patient is symptomatic.

CRITICAL INTERVENTIONS

- Quickly place a urinary catheter to relieve acute urinary retention.
- Use a coudé-tip catheter for difficult placement of the catheter if the prostate or bladder neck is the area of obstruction.

- Place a three-way irrigating catheter for treatment of gross hematuria with clots.
- Urinary obstruction with associated infection (pyonephrosis) is an emergency, necessitating prompt decompression of the collecting system by cystoscopy with ureteral stent or by placement of a PCN tube.
- Perform a RUG prior to attempts at urinary catheterization if there is any question about urethral integrity.

Common Pitfalls

- Overzealous attempts by staff to place a urinary catheter leading to the formation of a false passage.
- Failure to consult urology after unsuccessful attempts at catheter placement.
- Overuse of antibiotics in the asymptomatic patient with a chronic, colonized catheter.
- Failure to treat pyonephrosis promptly by decompression of the urinary collecting system.

ACKNOWLEDGMENT

We wish to acknowledge the work of Dr. Paul E. Pamphrus on the previous edition of this chapter.

SECTION XII
Gynecologic Emergencies

Section Editor: GREGORY W. HENDEY

CHAPTER 129 Pelvic Pain

Joseph C. Schmidt

CLINICAL PRESENTATION

Pelvic pain is a common emergency department (ED) presentation. It is often accompanied by various symptoms including fever, vomiting, dysuria, vaginal discharge, or bleeding. The practitioner must rapidly differentiate among etiologies that range from benign to life-threatening. This differentiation requires a complete but focused history and physical examination combined with a broad knowledge of potential disease processes to generate an appropriate differential diagnosis. This differential can then be tested by using appropriate diagnostic studies and generating an assessment and plan that will allow for the timely treatment and disposition of the patient.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of pelvic pain is broad and falls into two main categories. This discussion is focused on the presentation of acute pelvic pain, which by definition is pain of <6 months in duration. Chronic pelvic pain will be mentioned only in the context that a diligent evaluation of the patient with chronic pain must be accomplished to avoid missing a more worrisome complication or new diagnosis.

The differential diagnosis of acute pelvic pain encompasses multiple organ systems (Table 129.1). A useful organizational strategy is to divide the patients into functional categories according to reproductive status. This approach highlights the special

consideration of each group. Children and prepubertal adolescents have a number of unique issues (Table 129.2). Likewise, postmenopausal women are at risk for conditions that are uncommon in other age groups (Table 129.3). The remainder of the section highlights the most common and important etiologies in each category. It is important to remember that significant overlap between these categories does occur.

TABLE 129.1
Differential Diagnosis of Acute Pelvic Pain

Gynecologic/Obstetric

1. Pregnancy related
   a. Ectopic pregnancy
   b. Abortion, threatened or incomplete
   c. Septic abortion
2. Acute infections
   a. Endometritis
   b. Pelvic inflammatory disease
   c. Tubo-ovarian abscess
3. Adnexal disorders
   a. Hemorrhage/rupture of ovarian cyst
   b. Torsion of adnexa
   c. Twisted paraovarian cyst
4. Recurrent
   a. Mittelschmerz (midcycle pain)
   b. Primary/secondary dysmenorrhea
   c. Endometriosis

Gastrointestinal

Prepubertal

The approach to pelvic pain in the prepubertal patient requires attention to a broad spectrum of organ systems, though gastrointestinal and urologic causes are the most common. Significant gynecologic pathology is uncommon. Pelvic pain related to accidental perineal trauma is not uncommon, but a high index of

suspicion should be maintained for possible sexual abuse. Any suspicion of abuse warrants a complete investigation. In the peripubertal age group, complications of sexual activity should be considered. In this age group, symptoms surrounding menarche are also common. In younger children, vulvovaginitis can arise from chemical irritation (i.e., bubble bath) or a vaginal foreign body.

Reproductive Age

Gynecologic and obstetric etiologies of pelvic pain increase in frequency as women enter reproductive age.

Ectopic pregnancy (EP) is more fully discussed in Chapter 137. The classic presentation of EP is catastrophic pain in association with missed menses and vaginal bleeding. Multiple variations of this presentation are common. Early stretch and growth of the ectopic gestation in the fallopian tube can result in mild pain caused by tubal distention and contraction. Intermittent leaking of blood, which often precedes rupture by several days, will cause mild, focal, and intermittent peritoneal irritation, which is often poorly characterized by the patient. Risk factors for EP included a history of infertility, use of an intrauterine device, prior tubal ligation, or other pelvic surgery (1). Because of the diversity of presentations, almost one-half of ectopic pregnancies are missed on initial physician contact (2).

Miscarriage in any of its forms can cause pelvic pain. Examination of the cervical os may differentiate a threatened abortion (closed os) from an inevitable or incomplete abortion. Septic abortion presents with a tender, boggy, palpable uterus and fever. Traction on the round ligament and other pelvic structures as the uterus grows during pregnancy can cause significant but transient pain.

Torsion of the ovary or other adnexal structures is a gynecologic emergency. The pain associated with torsion is generally intense, severe, and unilateral, with frequent radiation to the back or thigh. The pain may be intermittent and associated with nausea and vomiting. An adnexal mass may be palpable. Common predisposing factors include pregnancy, ovarian hyperstimulation syndrome, and

ovarian or paraovarian cyst disease. Because the ovary and the kidney have the same innervation (T10 to T11), the clinical picture may mimic renal colic.

Pelvic inflammatory disease (PID) is discussed more fully in Chapter 130. A dull lower abdominal pain, most often bilateral, characterizes uncomplicated PID. Onset is more frequent within 1 week of menses, but the pain may be subacute and develop over several days. If infection extends beyond the endometrium and tubes, pain can become more severe and peritoneal irritation is seen. Clinical signs and laboratory parameters tend to be nonspecific and can include fever, vaginal discharge, cervical motion tenderness (CMT), uterine or adnexal tenderness, and, rarely, a mass. Risk factors include multiple sex partners, prior PID, young age, and either no contraception or the use of an intrauterine device (3,4).

Tubo-ovarian abscess (TOA) may occur with severe PID, particularly when caused by or associated with anaerobic organisms. TOA is the most common intra-abdominal abscess in premenopausal women. The mortality of PID has been reported to be as high as 8.6% when associated with rupture (5). Some TOAs are detected when PID fails to resolve with appropriate antibiotic treatment. In other cases, sterile hydrocele or pyosalpinx results from a remote acute infection. The most common signs and symptoms include abdominal pain, fever, and a palpable pelvic mass (6). Rupture of an abscess causes sudden, frank pain resulting from peritoneal contamination, and it is a gynecologic emergency.

Primary dysmenorrhea often occurs in adolescents, usually within 1 to 2 years of menarche. This diagnosis is very common, with 60% of menstruating women reportedly suffering some level of symptoms (7). Pain caused by myometrial contractions occurs just before or coincident with menstruation, and it is described as severe, crampy, and suprapubic. Pain tends to occur with every menstrual period and may be incapacitating, particularly for the first 1 to 2 days of menses. Secondary dysmenorrhea can occur at any age in a menstruating woman and is most often associated with endometriosis. The rate of dysmenorrhea decreases with increasing age. In a study of 165 university students aged 17 to 19 years,

dysmenorrhea caused absenteeism or loss of activity at least once for 42% of the women studied. The most significant associated risk factors were early age at menarche, long menstrual periods, smoking, alcohol intake, and obesity (greater than the 90th percentile) (8).

Sexual abuse has also been strongly associated with dysmenorrhea and chronic pelvic pain. In a study of 581 nonpregnant women aged 18 to 45 years with complaints of dysmenorrhea and chronic pelvic pain, there was a childhood incidence of sexual abuse of 26% and an adult incidence of 28% (9). Other studies also support a significant association between a history of sexual abuse and chronic pelvic pain (10).

Uterine myomata, or fibroid tumors, of the uterus are common, particularly during later reproductive years. Myomata often cause heavy, irregular, and crampy menses. These tumors may undergo ischemia, necrosis, hemorrhage, or torsion. Torsion of the fibroid causes a sharp increase in severity of pain. Physical examination in a patient with fibroids reveals a tender, enlarged, and often irregular uterus. Myomata may also interfere with fertility, increasing the risk of spontaneous abortions (11).

Mittelschmerz is unilateral adnexal pain at the time of ovulation, resulting from leakage of blood or fluid from the Graafian follicle. Sudden, sharp, well-localized peritoneal irritation is usually found without fever, hypotension, or signs of inflammation or infection. An adnexal mass is infrequent. Occasionally, symptoms can be severe and generalized, but they classically decrescendo and resolve within 24 to 48 hours. In some patients, midcycle pain is recurrent and predictable.

Ovarian cyst disease may occur at any age. Simple functional cysts may contain follicular fluid or blood. Corpus luteum cysts are extremely vascular; ruptured corpus luteum cysts are common in pregnancy, presenting with sudden unilateral pain that is usually mild and localized. Less common are dermoid cysts, endometriomas, and serous and mucinous cysts. With cyst rupture, rapid onset of pain is characteristic, and local peritoneal irritation is common, but fever and systemic signs are rare. Pain may be diffuse if cyst fluid or

blood contaminates the entire abdominal cavity. Rarely rupture with significant hemorrhage that may lead to hypovolemia and hemodynamic instability (12). Unruptured ovarian cysts may also cause pain if the cyst distends rapidly or if torsion occurs.

Appendicitis is the most common nonobstetric surgical emergency in pregnancy. It is particularly difficult to diagnose in women, reflected by the 25% to 50% negative laparotomy rate for women in reproductive years (13). Diagnosing appendicitis becomes more difficult as pregnancy progresses because the uterus obscures the examination and distorts the location. Delays in surgical management in pregnancy result in increased morbidity for both the mother and the fetus (2,13). CMT may occur in either PID or appendicitis, and pyuria occurs in 10% to 20% because of the proximity of the ureters to the adnexa and appendix. The presence of significant bilateral adnexal tenderness and longer symptom duration (>3 days) may suggest PID, but imaging or laparoscopy may be required to differentiate the two.

Urologic causes of pelvic pain include cystitis, pyelonephritis, and renal calculi. Pyelonephritis usually presents with suprapubic tenderness and costovertebral angle tenderness. Renal calculi typically cause severe unilateral, colicky pain. The patient may have a history of renal calculi, and hematuria is frequently present. A Bartholin gland cyst or abscess can cause incapacitating pelvic pain. The glands are located in the labia minora at approximately the 4 and 8 o'clock positions. Two potential ED treatment strategies are placement of a Word catheter or marsupialization of the cyst (14).

Postmenopausal

Pelvic pain in the postmenopausal patient adds a unique set of concerns to those already mentioned. In this age group, atrophic vaginitis is a common problem but should be a diagnosis of exclusion. Malignancies of both the reproductive and gastrointestinal systems increase with age. Urinary tract infections also increase in frequency; however, caution must be used in attributing symptoms to a questionable urinalysis. Diverticulitis can

occur in younger women but is more common in this age group. Finally, ischemic bowel must be considered, especially when pain is out of proportion to the physical examination findings.

ED EVALUATION

An appropriate history includes a description of the pain—onset, progression, quality, character, intensity, and radiation—as well as the reason for the ED presentation. The menstrual history includes gravidity, parity, date, and duration of the last two menstrual periods; regularity; any recent menstrual abnormalities; as well as time of menarche and menopause, when applicable. A history of sexually transmitted diseases (STDs), use and type of contraceptives, recent vaginal discharge, breast symptoms, dyspareunia, and urinary complaints should be obtained. Gastrointestinal complaints must also be evaluated, including nausea, vomiting, diarrhea, or constipation. A history of fever and chills should be noted.

The physical examination should be direct but complete. General appearance may be helpful, although individual pain thresholds vary greatly. The patient who avoids movement may have peritoneal irritation, whereas the patient rocking in distress suggests a viscus under pressure. Alterations in vital signs may help identify systemic infection, sepsis, or significant hypovolemia. Abdominal, pelvic, and rectal examinations are mandatory in all women with pelvic pain.

The abdominal examination should focus on a search for masses or palpable organs, localizing areas of tenderness, and demonstrating peritonitis. Peritonitis is detected by performing maneuvers that move the peritoneum but do not put pressure on visceral organs (heel tap, cough, light percussion, pelvic jarring, and general patient movement). “Rebound” tenderness has been the classic procedure for demonstrating peritoneal irritation, yet it may be the least accurate for diagnosing peritonitis. Interobserver variability is substantial, and the test causes unnecessary pain in patients with potentially surgical disease (15).

The pelvic examination should include inspection of the external genitalia as well as the introitus and cervix. The bimanual examination assesses uterine size, palpable masses, and CMT. CMT is often considered pathognomonic of PID, but other diseases such as appendicitis, cyst rupture, and EP also produce pelvic–peritoneal irritation and CMT. A uterus that is fixed and poorly mobile often indicates adhesions secondary to endometriosis, tumor, or prior infection. Rectal examination involves palpation for focal pain, masses, induration, nodularity, or blood.

A sensitive qualitative pregnancy test (urine or serum) for the β-subunit of human chorionic gonadotropin (β-HCG) is essential for evaluation in all women of childbearing age. With a low threshold (<50 mIU/mL International Reference Preparation), false-negative pregnancy tests occur in <1% of patients, even with an abnormal pregnancy (ectopic or miscarriage). A quantitative serum β-HCG may also assist in the interpretation of ultrasound results in first-trimester pregnancies and allow tracking of pregnancy progression at follow-up. Significant pelvic pathology may exist despite a normal complete blood count. However, an increased white blood cell count may reflect systemic infection, and chronic blood loss may be suspected if a low hematocrit is obtained.

An uncontaminated urinalysis is needed to diagnose a urinary tract infection and may assist in differentiating renal colic from ovarian torsion. Vaginal wet mount can indicate various causes of vaginitis (rarely a cause of pelvic pain, but possibly a marker for STD exposure). Cervical cultures or tests to detect *Neisseria gonorrhoeae* and *Chlamydia trachomatis* may assist in the diagnosis of PID.

Pelvic ultrasound is the primary imaging modality if the suspected etiology involves the reproductive tract. Emergency physicians increasingly perform these tests, and several studies have suggested that this practice is safe, accurate, and efficient (16–18). Transvaginal ultrasound can reliably identify intrauterine pregnancy in the first trimester. A gestational sac and fetal pole should be seen by 5 weeks, and fetal heartbeat should be seen by approximately 8 weeks. Pelvic ultrasound is also adept at identifying adnexal masses

and, with the use of Doppler flow technology, can confirm perfusion of the ovaries.

CT may be useful in the diagnosis of pelvic pain of otherwise unclear etiology. CT has become the primary imaging modality for renal colic, and it is an appropriate study when appendicitis or other bowel pathology leads the differential diagnosis.

Laparoscopy is the gold standard study in the diagnosis of pelvic pain. Laparoscopy remains the procedure of choice to confirm the diagnosis for the patient who is acutely ill or for whom surgical disease (e.g., appendicitis) cannot be excluded. In a study of laparoscopic examination of 316 women with acute pelvic pain, >76% had an abnormal laparoscopic examination, and 45% of those with abnormal laparoscopic examinations had EP (19).

KEY TESTING

- Urinalysis and pregnancy testing
- Pelvic ultrasound, CT scan, or laparoscopy in selected cases

ED MANAGEMENT

The ED treatment of the patient with pelvic pain can be broken down into several critical questions.

Is the Patient Hemodynamically Stable?

Large-bore intravenous access, monitoring, and crystalloid fluid resuscitation are the first steps in managing the unstable pelvic pain patient. Early operative intervention is indicated when patients are persistently unstable. When multiple etiologies are being considered, it is reasonable to simultaneously consult the appropriate services.

Is the Patient Pregnant?

Early establishment of pregnancy status is critical. It should occur as early as possible and occur concurrent with resuscitation when

necessary. A positive pregnancy test requires effort to be focused first on confirming or excluding EP.

Does the Patient Have Severe Pain or Peritoneal Signs?

The presence of peritonitis requires a diligent search for surgically correctable etiologies. Early consultation for consideration of direct operative evaluation is prudent. Atypical presentations or severe pain without evidence of peritoneal irritation may require appropriate imaging studies to further focus the differential diagnosis. Pain control should be a primary goal, and evidence suggests analgesia may improve diagnostic accuracy (20).

Does the Pelvic Examination Reveal Evidence of Infection?

Pelvic examination findings suggestive of PID in the absence of severe pain or peritonitis can be treated by a number of approved regimens (see Chapter 130). Imaging in PID is limited to the evaluation of possible complications such as TOA.

Does the Patient Have an Alternative Diagnosis?

An alternative diagnosis should be considered in the stable, nonpregnant patient with mild-to-moderate symptoms and no evidence of PID. Urologic and gastrointestinal etiologies are most common. If other diagnoses are reasonably excluded, symptom control and outpatient referral are indicated.

CRITICAL INTERVENTIONS

- Provide aggressive resuscitation and monitoring of unstable pelvic-pain patients

DISPOSITION

Admission is necessary for potential surgical disease, including appendicitis, selected cases of PID, and EP associated with significant symptoms.

Observation may be necessary if a surgical etiology is possible, pain remains severe, or vomiting and other signs of systemic toxicity are worrisome to the clinician. Observation is appropriate for patients with focal peritonitis secondary to presumed cystic rupture or for suspected early appendicitis. Patients observed in the ED should have serial examinations and clear criteria for admission.

If a patient is discharged from the ED with pelvic pain in which the etiology is uncertain but the patient is stable, instructions for appropriate and early follow-up are imperative. Any woman with abdominal pain who is discharged from the ED must be instructed to obtain a repeat evaluation if her pain continues or worsens. Because many causes of pelvic pain, particularly when the pain is chronic, are not amenable to ED diagnosis, there will exist a population of patients for whom exclusion of surgical disease, short-term pain relief, and referral for definitive diagnosis are the appropriate actions in the ED.

Common Pitfalls

- Failing to recognize the severity of illness by relying inappropriately on vital signs.
- Failing to obtain pregnancy testing particularly around the time of menarche and menopause or in those who report birth control use or history of sterilization procedures.
- Attributing pelvic pain to urinary tract infection when the urinalysis is questionable and other causes have not been ruled out.
- Failing to recognize that CMT is neither specific nor sensitive for PID.

CHAPTER 130

Pelvic Inflammatory Disease

Alfred Sacchetti

Pelvic inflammatory disease (PID) is a generic term that describes infection-related inflammatory changes of the upper genital tract in women. PID may include any combination of endometritis, salpingitis, tubo-ovarian abscess, or pelvic peritonitis. In the majority of cases *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are implicated; however, PID may also be caused by other organisms, including anaerobic bacteria, *Gardnerella vaginalis, Haemophilus influenzae,* enteric gram-negative rods, *Streptococcus agalactiae, Mycoplasma hominis, Mycoplasma genitalium,* and *Ureaplasma urealyticum* (1). More than 100 aerobic and anaerobic bacterial strains have been recovered from the pouch of Douglas or high cervical cultures in patients with PID (2). Sexually transmitted infections (STIs), including PID are most common in the second and third decades of life, with most cases in women under 25 years of age. In 2011 the prevalence of chlamydial infections was 648.9 per 100,000 women and gonorrhea was 104.2 per 10,000 for both sexes (3–5). Child abuse must be suspected in any prepubertal female with the diagnosis of salpingitis.

Most pelvic infections originate from colonization of the vagina or cervix. From this site, the pathogens ascend through the cervical os into the lower uterine segment and uterine cavity. Normal cervical mucus presents a natural barrier to vaginal organisms; however, both *N. gonorrhoeae* and *C. trachomatis* appear able to produce uterine infections despite this protection. Certain cervical

conditions, including recent menses, surgical cervical procedures, foreign bodies (intrauterine devices [IUDs]), and various hormonal changes during a menstrual cycle, decrease the defensive ability of the cervix. The hormonal changes induced by oral contraceptive agents enhance rather than reduce the bacteriostatic properties of the cervix if administered prior to colonization. There is evidence that oral contraceptives may mask the symptoms of chlamydial infection once it does become established.

Once entry into the uterus has been gained, the uterine lining becomes inflamed. In postpartum patients, the myometrium becomes infected, but in other patients, this inflammation is seldom invasive and is limited to the endometrium. The inflammation may produce uterine bleeding, but in the nongravid uterus, this is seldom clinically significant. The pathogens then continue their migration through the fallopian tubes. In the case of mycoplasmal infection, ascension may occur by way of parametrial structures rather than through the uterine cavity.

Initially, tubal infection is limited to the mucosa of the lumen, but the inflammation rapidly extends through the full thickness of the tubes. This transmural reaction of the fallopian tubes often causes the early pain of pelvic infection. The inflammation initiated by *N. gonorrhoeae* or *C. trachomatis* frequently overwhelms the normal uterine defense mechanisms and results in infections from opportunistic pathogens, particularly *Bacteroides* sp (6).

In severe cases of salpingitis, the purulent material from the fallopian lumens exudes through the open fimbriae into the abdominal cavity, producing peritonitis. The infection of the endometrium and fallopian tubes results in an inflammation of the surrounding parametrial structures. Although these structures may not undergo actual infection by the invading pathogens, their proximity to the true infection produces a severe parametritis in many patients. Escape through the end of the right fallopian tube and ascension to the right colic gutter may result in inflammation around the liver. *Fitz-Hugh–Curtis syndrome* (perihepatitis) is usually associated with *C. trachomatis* but may occur in 8% to 10% of all cases of salpingitis. Although typically associated with STIs, this

syndrome may result from any intra-abdominal inflammatory process (7).

Inflammation and stagnation of host defenses, particularly in the fallopian tubes, allow for the possibility of unchecked bacterial growth. A tubo-ovarian abscess may develop; originating in the fallopian tube, the abscess may extend to involve the fimbriae and ovary as well. The bacterial content of a tubo-ovarian abscess is mixed, with a preponderance of anaerobes (4).

CLINICAL PRESENTATION

A clinical diagnosis of PID may be difficult because of the wide variation in signs and symptoms. No single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID. The Centers for Disease Control and Prevention (CDC) estimate that a clinical diagnosis of PID has a positive predictive rate of 65% to 90% for salpingitis when compared to laparoscopy (1). In a separate study, clinicians failed to recognize *N. gonorrhoeae* or *C. trachomatis* in 38% of infected women and overtreated 88% of women with no infection from these pathogens (8). Similarly in a review of only emergency department encounters, laboratory specimens confirmed infections for gonorrhea in 4.4%, for chlamydia in 10%, and for both in 2.6% of patients with a diagnosis of PID (9). Mild or nonspecific complaints may go unrecognized by the clinician (e.g., abnormal bleeding, dyspareunia, or vaginal discharge). Most authorities recommend a low threshold for diagnosis of PID because of the long-term effects and potential damage to the reproductive system of women. The CDC now recommends empiric treatment for PID if no other explanation can be found for lower abdominal pain in sexually active females with cervical motion tenderness, uterine tenderness, or adnexal tenderness. Table 130.1 summarizes findings consistent with PID.

TABLE 130.1
Diagnostic Findings in Pelvic Inflammatory Disease (PID)

Minimal Criteria for the Clinical Diagnosis of PID

Empiric treatment of PID should be instituted in sexually active females considered at risk for an STI who have lower abdominal or pelvic pain and one or more of the following findings.

Cervical motion tenderness

Uterine tenderness

Adnexal tenderness

Additional Criteria

The presence of more severe clinical signs warrant more elaborate diagnostic evaluations and more aggressive treatment to assure the correct diagnosis and prevent possible morbidities.

Oral temperature >38.3°C (101°F)

Abnormal cervical or vaginal mucopurulent discharge

Presence of white blood cells on saline microscopy of vaginal secretions

Elevated erythrocyte sedimentation rate

Elevated C-reactive protein

Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*

PID-Specific Criteria

Histopathologic evidence of endometritis on endometrial biopsy

Tubo-ovarian abscess, thickened or fluid-filled tubes on transvaginal sonography, magnetic resonance imaging (MRI), or other radiologic tests

Laparoscopic abnormalities consistent with PID

Adapted from Centers for Disease Control and Prevention. Sexually Transmitted Disease Guidelines 2010. Available online at http://www.cdc.gov/std/treatment/2010/pid.htm.

Although attempts have been made to distinguish between features of infection caused by *N. gonorrhoeae* and *C. trachomatis,* they have not been consistent or reliable. *N. gonorrhoeae* salpingitis develops in the first few days after menses, producing a purulent vaginal discharge and severe pelvic pain. *C. trachomatis* infection may occur at any point in the menstrual cycle and results in less cervical discharge and milder symptoms. More important, however, is that both of these infections frequently coexist in 35% to 42% of patients (10).

The patient with a pelvic infection almost invariably presents to the ED with a complaint of lower abdominal pain. Inflammation of the endometrium, fallopian tubes, and parametrial structures usually produces diffuse bilateral pelvic pain. When questioned,

most women describe a dull, constant, poorly localized pain, although almost any characterization of the pain has been reported. Because of the sensitive nature and social stigma of STIs, physicians should be empathetic and tactful in eliciting the patient's history. Pelvic pain is seldom the only presenting complaint. *N. gonorrhoeae* or *C. trachomatis* cervicitis results in a vaginal discharge in over 50% of patients, whereas abnormal vaginal bleeding is seen in 30%. Gastrointestinal complaints, including nausea and vomiting, are less common but may be present. Urinary tract symptoms are common, with 20% of laparoscopically proven pelvic infections associated with irritative voiding symptoms (10). Pelvic infection should be suspected in patients who complain of dysuria or suprapubic pain that occurs only during micturition. Classic urinary tract presentations including urgency, frequency, and dysuria have been reported in 33% to 53% of women found to have STI.

A temperature greater than 38°C (100.4°F) is found in only 33% of patients. Fever supports the diagnosis but does not confirm it, nor does its absence preclude the diagnosis of PID. The abdominal examination commonly reveals tenderness in both lower quadrants, although one side may be more tender. Peritoneal signs indicate a more severe infection, with free exudate in the pelvis or abdomen, and intraperitoneal extension should be considered. If perihepatitis is also present, there may be tenderness in the right upper quadrant.

Pelvic examination must be approached carefully if meaningful information is to be gained. Because of pain or previous experience, this examination may be very difficult for many patients. Speculum examination may reveal a vaginal discharge. A markedly inflamed purulent cervix is indicative of an acute cervicitis and is supportive of some degree of pelvic infection. Normal appearing cervical discharge, and the absence of white blood cells on either Gram stain or a saline preparation of vaginal fluids, makes the diagnosis of PID very unlikely (1).

Bimanual examination begins with careful testing for cervical motion tenderness. Gentle motion of the cervix should be attempted initially, as an overly aggressive examination may produce reflexive guarding by the patient and severely limit the remainder of the

evaluation. Elicitation of pain with either lateral or anteroposterior motion of the cervix is sensitive but not specific for pelvic infection. The emergency physician must remember that other causes of pelvic irritation: fluid from ruptured cysts, appendicitis, and blood from ectopic pregnancies can also produce this sign. The uterus is frequently firm but tender. Bilateral adnexal tenderness is one of the most consistent physical findings in studies evaluating diagnostic criteria for salpingitis. An adnexal mass may be appreciated but is not a consistent finding. Findings on pelvic examination may be atypical in patients who have had multiple prior infections or tubal ligation. Obstruction of the fallopian tube may prevent extension of the infection beyond the proximal tube, limiting the degree of adnexal tenderness.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of lower abdominal pain in women should include at least three possibilities: (a) ectopic pregnancy, (b) PID, and (c) appendicitis. Ovarian cyst, urinary tract infection, gastrointestinal hernia, and ovarian torsion should also be considered. Ectopic pregnancy is addressed in Chapter 137, and the approach to pelvic pain is described in Chapter 129. All women with pelvic pain, regardless of their menstrual history, should have a pregnancy test; the only exception is the woman who has had a hysterectomy (1). Salpingitis is the most common incorrect diagnosis in missed ectopic pregnancy and should be considered only after ectopic pregnancy has been excluded (1). The coexistence of infection and pregnancy is possible but unusual, because a mucous plug forms after implantation, preventing the spread of lower genital infections into the upper genital system. However, there is a brief window between insemination and mucous plug formation during which infection may occur. Appendicitis may be differentiated from PID by its unilateral nature, but this is by no means diagnostic.

ED EVALUATION

When PID is suspected, additional support for the diagnosis may be obtained through laboratory analysis. Because of the time interval between the collection of specimens and the return of results, a system should be in place for follow-up of patients undergoing any STI-related testing.

Gonorrhea cultures are obtained by placement of a sterile swab 1 to 2 cm into the endocervical canal, with rotation of the swab for 10 to 30 seconds. Following collection, the swab should be immediately plated on either chocolate agar or Thayer–Martin agar.

Chlamydia detection techniques include culture, antibody detection (enzyme-linked immunosorbent assay [ELISA] and fluorescent), and nucleic acid probes. In contrast to gonorrhea testing, nonculture techniques are the preferred detection procedures for the diagnosis of *C. trachomatis.*

Nucleic acid probe tests have been developed for both of these organisms. These tests are very sensitive and specific and may be applied not only to cervical specimens but also to urine and vaginal swabs. The additional advantage of this testing technique is that it permits home screening of patients for STIs (11–13).

Additional laboratory studies should include urinalysis to rule out urinary tract infection and a urine or serum pregnancy test. A complete blood count may be obtained for use in some disposition decisions, but the clinician should recognize that the test has limited usefulness. Serology for syphilis and human immunodeficiency virus (HIV) testing should be considered in patients with clinical PID or arranged at follow-up for those with laboratory-proven infections.

Imaging studies are helpful in patients with severe symptoms and those in whom the diagnosis is in question. Ultrasonographic findings indicative of PID include thickened fluid-filled fallopian tubes, free pelvic fluid, and tubal hyperemia. Cases progressing to tubo-ovarian abscesses may also demonstrate a complex adnexal mass, echogenic cul-de-sac fluid, and pyosalpinx (1,14). Computerized tomography may be needed in some patients in whom PID cannot be distinguished from appendicitis or other gastrointestinal pathology.

KEY TESTING

- Urine or serum pregnancy testing
- Gonorrhea and chlamydia testing
- Ultrasound or CT as needed to exclude tubo-ovarian abscess or appendicitis

ED MANAGEMENT

Treatment regimens for PID change periodically and it is advisable to monitor the recommendations of the CDC as well as local health agencies regarding treatment of STIs. *N. gonorrhoeae* has continued to demonstrate increasing resistance to all classes of antibiotics including quinolones and cephalosporins (15). Table 130.2 contains the 2010 treatment guidelines for PID. The management of acute pelvic infection centers on prompt antibiotic therapy directed against both *N. gonorrhoeae* and *C. trachomatis*. The goal of treatment is to prevent continued or worsened infection and limit the complications of PID, including chronic pain, ectopic pregnancy, infertility, and chronic infection.

TABLE 130.2
Antibiotic Therapy of Pelvic Inflammatory Disease

Parenteral Treatment
Regimen A
Cefotetan 2 g IV every 12 hrs
OR
Cefoxitin 2 g IV every 6 hrs
PLUS
Doxycycline 100 mg PO or IV every 12 hrs
Regimen B
Clindamycin 900 mg IV every 8 hrs
PLUS
Gentamicin IV/IM 2 mg/kg load followed by 1.5 mg/kg q8h. Single daily dosing (3–5 mg/kg) may be substituted
Alternative Regimen
Ampicillin/sulbactam 3 g IV every 6 hrs
PLUS
Doxycycline 100 mg PO or IV every 12 hrs
Oral Treatment
Regimen A
Ceftriaxone 250 mg IM
PLUS
Doxycycline 100 mg PO twice daily for 14 d
WITH or WITHOUT
Metronidazole 500 mg PO twice daily for 14 d
Regimen B
Cefoxitin 2 g IM along with probenecid 1 g PO
PLUS
Doxycycline 100 mg PO twice daily for 14 d
WITH or WITHOUT
Metronidazole 500 mg PO twice daily for 14 d
Regimen C
Alternate third-generation cephalosporin such as ceftizoxime or cefotaxime may be substituted depending on hospital formulary
PLUS
Doxycycline 100 mg PO twice daily for 14 d
WITH or WITHOUT
Metronidazole 500 mg PO twice daily for 14 d
Patients with severe allergic reactions to cephalosporins are rare and occur in <5% to 10% of patients with historical penicillin allergies. Patients who do not tolerate cephalosporins may be treated with spectinomycin 2 g IM. If spectinomycin is not available, then azithromycin 2 g orally may be effective. Use of azithromycin should be extremely limited to prevent emergence of resistance to this organism. Again these patients need to be followed carefully.[a]

[a]Recommendations for cephalosporin allergic patients adapted from Centers for Disease Control. Updated recommended treatment regimens for gonococcal infections and associated conditions: United States, April 2007. Available online at http://www.cdc.gov/std/treatment.

Adapted from Centers for Disease Control and Prevention. Sexually Transmitted Disease

Treatment of uncomplicated cervicitis or urethritis with single-dose antibiotic regimens has been described. Options reported include oral azithromycin (1 g), plus cefpodoxime (400 mg) or cefuroxime axetil (1 g). In penicillin-allergic patients, the use of a single 2-g dose of azithromycin has also been described, although there are fears that this may only precipitate resistance (16). The clinician may consider such therapies more convenient; however, none of these have been formally endorsed by the CDC for upper tract or established pelvic infections (1).

Patients coinfected with HIV do not require any significant modifications in their treatment regimens for PID. These patients are more likely to have infections with *M. hominis, Candida* and *Streptococcal* sp, and human papillomavirus (HPV). However, disposition and determination of the need for hospitalization should be based on the patient's overall clinical condition and not the presence of both PID and HIV.

The presence of an IUD has been reported to increase the incidence of pelvic infections, although this effect appears to be limited to the first 3 weeks after insertion of the device. There is no evidence that an IUD needs to be removed in a patient diagnosed with an acute upper genital tract infection. However, close follow-up with gynecologic consultation appears prudent in these patients (17).

Because infected males may be asymptomatic or deny symptoms, women with pelvic infections are at risk for reinfection if they continue relations with an infected male. Empiric treatment is recommended for any male who has had sexual contact with a woman diagnosed with a pelvic infection in the 60 days prior to her manifestation of symptoms (1).

CRITICAL INTERVENTIONS

- Rule out tubo-ovarian abscess in patients with PID and severe unilateral pelvic tenderness.

- Initiate parenteral antibiotics for toxic patients with PID and for those with tubo-ovarian abscess.
- Initiate empiric antibiotic treatment for patients suspected of having PID, pending return of confirmatory test results and having early follow-up arranged.

DISPOSITION

Suggested criteria for admission are listed in Table 130.3. Hospitalization is frequently indicated for pregnant patients. There are no data to recommend inpatient management over outpatient therapy for adolescent patients.

TABLE 130.3
Admission Criteria for Patients with PID

1. Surgical emergencies (e.g., appendicitis) cannot be excluded.
2. Pregnancy.
3. Patient does not respond clinically to oral antimicrobial therapy.
4. Patient unable to follow or tolerate an outpatient oral regimen.
5. Patient has severe illness, nausea and vomiting, or high fever.
6. Patient has tubo-ovarian abscess.

Note: None of these criteria is absolute; all should be applied on an individual basis.
Clinical criteria for improvement within 72 hours consist of defervescence, reduction in direct or rebound abdominal tenderness, and reduction in uterine, adnexal, and cervical motion tenderness within 3 days of initiation of therapy.
Adapted from Centers for Disease Control and Prevention. Sexually Transmitted Disease Guidelines 2010. Available online at http://www.cdc.gov/std/treatment/2010/pid.htm.

Outpatient management is appropriate for those patients not meeting criteria for admission shown in Table 130.3. All discharged patients should receive follow-up care to ensure response to treatment. If cultures are obtained, a mechanism should be in place to ensure that patients and their physicians or the public health department are notified of positive results.

Common Pitfalls

- The differential diagnosis of women thought to have PID must include ectopic pregnancy and appendicitis.

- The clinician should question the diagnosis of PID in any patient with unilateral pelvic pain.
- Pregnancy must be ruled out.
- Serologic testing for syphilis and HIV testing counseling are indicated for most women with a documented sexually transmitted disease.

CHAPTER 131

Vaginal Bleeding in the Nonpregnant Patient

Eric Anderson and Margaret McKenzie

Vaginal bleeding from multiple causes is a common problem encountered in emergency medicine (1). Abnormal uterine bleeding affects 20% to 30% of women at some time during their reproductive years (2). It is incumbent upon the emergency physician to rapidly distinguish between life-threatening bleeding and bleeding that can be evaluated in the emergency department (ED) and referred for further evaluation by a gynecologist. Complications of symptomatic vaginal bleeding include iron-deficiency anemia, fatigue, depression, and disturbance in sexual function, as well as disturbances of social and occupational activities (3).

CLINICAL PRESENTATION

Important considerations when evaluating vaginal bleeding in the emergency setting include understanding the various etiologies of such bleeding presentations. Pregnancy must be ruled out in all women of childbearing age. Abnormal vaginal bleeding may or may not be associated with the menstrual cycle. Bleeding that occurs at the usual time of menses but is more copious or longer than usual is termed *menorrhagia.* Bleeding that occurs at irregular intervals or between normal menses is termed *metrorrhagia,* while irregular and excessive bleeding (>80 mL of blood per cycle) is termed *menometrorrhagia. Oligomenorrhea* is decreased menstrual frequency,

while *polymenorrhea* is increased menstrual frequency. Menstrual blood loss of less than 5 mL per cycle in termed *hypomenorrhea.* Normal cycle values are illustrated in Table 131.1. Variation in the use and definitions of these terms has prompted the development of a new classification system, PALM COEIN, to describe abnormal uterine bleeding based on the etiology. This acronym signifies Polyp, Adenomyosis, Leiomyoma, Malignancy and hyperplasia, Coagulopathy, Ovulatory disorder, Endometrial, Iatrogenic and Not yet classified as potential causes for the abnormal vaginal bleeding (4). This classification is based on anatomic (PALM) and physiologic (COEIN) findings which may not be known at the time of ED evaluation.

TABLE 131.1
Normal Menstrual Cycle Values

	Normal (5th to 95th Percentile)	Abnormal
Frequency of menses (d)	24–38	<24 or >38
Duration of flow (d)	4.5–8	<4.5 or >8
Blood loss (mL)	5–80	<5 or >80
Menarche onset age (yr)	9–14 (mean 12.9)	<8, >14

Frequency, duration, and blood loss: Adapted from Munro M. Classification of menstrual bleeding disorders. *Rev Endocr Metab Disord*. 2012;13:225–234.

Abnormal bleeding due to anovulation is more typically variable and the amount and timing of the bleeding is less predictable and is a common cause for the vaginal bleeding that presents to the Emergency room (3). Anovulatory cycles occur more commonly in perimenarchal and perimenopausal patients as well as patients with metabolic abnormalities like the classic polycystic ovarian syndrome. In perimenarchal girls anovulatory bleeding occurs as a result of immaturity of the hypothalamic–pituitary–ovarian axis.

DIFFERENTIAL DIAGNOSIS

It is imperative that the emergency physician determine whether the presenting vaginal bleeding is a complication of pregnancy. A

pregnancy test should be performed on all reproductive age patients regardless of the stated history of sexual activity. It is best to interview adolescent patients about sexual activity, alcohol and illicit drug use without parents present. It may be appropriate to ask parents if they suspect sexual activity alcohol or illicit drug use separate from the patient as well.

Sexually transmitted infections (STIs) are usually included in the differential diagnosis of vaginal bleeding. However, a recent article calls that dogma into question. Bernwald et al. studied *Chlamydia trachomatis* and *Neisseria gonorrhea* rates in ED patients. The patients with and without vaginal bleeding had comparable rates of STI (6).

The normal menstrual cycle is characterized by growth of the endometrium under the influence of estrogen. After ovulation progesterone increases and the endometrium matures. At the end of the cycle, estrogen and progesterone levels decrease and the endometrial surface sloughs resulting in menstruation. The transition to menopause is marked by unopposed estrogen stimulation of the endometrium which results in sporadic anovulatory cycles. In the absence of progesterone this results in unpredictable endometrial sloughing and vaginal bleeding (7).

Approximately 10% of bleeding in postmenopausal patients will be found to be related to a gynecologic or metastatic malignancy. Eighty to ninety percent of patients diagnosed with endometrial cancer present with vaginal bleeding (8–10). Endometrial cancer is the most common gynecologic malignancy with a lifetime incidence of 2.6% in women of the United States (7). It is followed by cancer of the ovary, cervix, and vagina in descending order (7). Ovarian cancer is the leading cause of gynecologic deaths. Vaginal cancer is usually metastatic from another primary source (7).

Women with various bleeding disorders often present to the ED with menorrhagia. Von Willebrand disease (VWD), a platelet adhesion disorder, occurs in 13% of women with chronic menorrhagia (11,12). Conversely 74% to 92% of women with VWD experience menorrhagia. VWD is the most common inherited bleeding disorder worldwide. It has been estimated that approximately half of patients presenting with unexplained

menorrhagia had a defect in platelet aggregation and/or release (12).

Systemic illnesses that can manifest as vaginal bleeding include marked obesity, hypothyroidism, hyperthyroidism, and liver cirrhosis with resulting coagulopathy.

Iatrogenic causes of uterine bleeding include oral, subdermal, or injectable sex steroids used for contraception hormone replacement therapy, treatment of hirsutism, dysmenorrhea, premenstrual syndrome, acne, or endometriosis (1). There may be transient abnormal bleeding for 1 to 2 cycles after emergency contraception use of levonorgestrel oral or intrauterine (13,14).

Bleeding from cervical polyps can occur as a result of coitus and may be minor or copious, while endometrial polyps present with intermenstrual bleeding. The presence of benign uterine lesions including polyps and fibroids peaks between 40 and 50 years of age even though they can occur at any age (15).

ED EVALUATION

Pregnancy status should be assessed in all reproductive age women presenting to the ED with a complaint of vaginal bleeding. Important historical elements include date of last **normal** menstrual period, sexual activity, prior pregnancies, and STIs. Details of the presenting bleeding history should include questions that might suggest orthostatic symptoms, when bleeding started, if bleeding is constant or intermittent, presence and description of abdominal pain, presence of foul vaginal discharge, and use of sex steroids or recent discontinuation of sex steroids or other inciting factors. Questions about the amount of bleeding, beyond spotting versus frank bleeding, are of limited value and often inaccurate (16). History should be taken without family and friends in the room as the patient may want to keep private certain elements of her sexual and reproductive history. Adolescents should be questioned in private for the same reasons. History of physical assault, sexual abuse, and genitourinary trauma should be obtained (Table 131.2).

TABLE 131.2
Causes of Nonpregnancy-Related Vaginal Bleeding

Anatomic	Congenital anomalies, polyps (uterine, cervical, urethral prolapse, uterine fibroids)
Coagulopathy	DIC, leukemia, thrombocytopenia, von Willebrand disease, thrombotic thrombocytopenic purpura, and immune thrombocytopenic purpura, prothrombin deficiency
Endocrine	Addison disease, congenital adrenal hyperplasia, Cushing syndrome, diabetes (poorly controlled), hyperprolactinemia, hyperthyroidism, hypothyroidism, polycystic ovary disease, primary ovarian dysfunction, postnatal withdrawal of maternal hormones
Foreign bodies	Condoms, cotton balls, IUD, sexual device, tampon, tissue paper, toy
Hormonal	Administration of exogenous sex steroids, anovulatory cycle
Infections	Cervicitis, chlamydia, condyloma acuminatum, gonorrhea, trichomonas, tuberculosis, UTI, vaginitis
Medications	Birth control pills, coumadin, heparin, phenobarbital, phenytoin
Neoplasm	Cervix, uterine, vagina, metastatic or erosive from elsewhere
Trauma	Blunt, sharp, sexual trauma
Other	Crohn disease of vulva, emotional stress, excessive dieting, excessive exercise, premature menarche (children)

DIC, disseminated intravascular coagulation; IUD, intrauterine device; UTI, urinary tract infection.

Upon physical examination those who appear pale, weak, tachycardic, or hypotensive should be assumed to have experienced a significant blood loss and attended to in a timely fashion. Pale conjunctivae, pale skin, and diaphoresis all imply a significant blood loss. Examination of the abdomen, perineum, and pelvis may reveal the cause of the bleeding or guide further testing. A rectal examination may be needed if there is no sign of blood on the pelvic examination. It may be necessary to obtain a catheterized urine specimen in patients who insist on vaginal bleeding but have no evidence of blood on pelvic or rectal examination. Skin should be examined for bruises that may indicate a coagulopathy or physical abuse.

Laboratory assessment in the uncomplicated patient should include a urine pregnancy test and possibly a urinalysis. Unstable

patients require a workup to assess the amount of bleeding and preliminary evaluation of the cause of the bleeding. Complete blood count (CBC), clotting studies, electrolytes, pregnancy test, and type and screen should be performed in unstable patients. Liver and thyroid function studies are useful in the minority of patients where these etiologies of the bleeding are a possibility.

Imaging with ultrasound may be useful in the patient with suspected uterine fibroids, polyps, mass or cervical or vaginal masses, or vascular malformations. Imaging with CT or MRI is useful in further delineating the etiology and extent of a mass or vascular malformation that may contribute to the bleeding.

KEY TESTING

- Urinalysis and pregnancy testing
- CBC, coagulation studies, and type and screen in those with significant blood loss

ED MANAGEMENT

The vast majority of patients will not present with life threatening bleeding and so will be evaluated and discharged home for outpatient follow up. A through history, physical examination, and pregnancy testing.

Treatment for patients in hemorrhagic shock should be initiated with two large bore IVs and fluid resuscitation and blood and blood products as needed. Early gynecologic consultation should be made as there are several treatment options in these patients.

Once resuscitation has begun, priority is to prevent and decrease further blood loss. Immediate interventions include examination under anesthesia to properly locate the source of the bleeding in cases of excessively heavy bleeding. Intrauterine Foley balloon placement is effective at significantly decreasing acute blood loss (17). IV administration of high-dose conjugated estrogen stopped abnormal uterine bleeding in 71% of women compared to 38% in placebo group (18,19). Dosage is 25 mg IV every 6 hours for 24 hours followed by oral combined estrogen/progestin therapy. Side

effects include nausea and vomiting which can be treated with antiemetics.

In cases where patients are poor surgical candidates, but are stable enough, uterine artery embolization offers a solution to control acute heavy bleeding until medical therapy can be effective (20). Hysterectomy is a last ditch alternative when therapy for acute heavy bleeding fails and fertility is no longer desired.

Since 40% to 80% of women treated for heavy menstrual bleeding have no anatomic pathology, pharmacologic therapy represents a great treatment alternative in the emergency setting (21). Nonsteroidal anti-inflammatory drugs (NSAIDs) work by decreasing prostaglandin levels in the endometrium and have been shown to decrease menstrual blood loss by at least 30% when compared to placebo (18,21). Doses include naproxen 250 to 275 mg or ibuprofen 200 to 400 mg or mefenamic acid 500 mg three times daily starting 24 to 48 hours prior to the onset of menstrual blood flow.

Tranexamic acid, an antifibrinolytic agent, inhibits endometrial plasminogen activator, thus stabilizing clots and represents an attractive option in the emergency setting. Oral forms are now approved for use in the United States and are advantageous because of the oral dosing and fast onset of action, with relatively few side effects. Its use is contraindicated in patients with active thromboembolic disease. Current dosing regimens for tranexamic acid are two 650 mg tablets orally for three times daily for a maximum of 5 days per cycle. Studies show a 40% reduction in menstrual blood loss compared to placebo (18,22).

Desmopressin is a synthetic analog of vasopressin and can be used to manage severe acute heavy vaginal bleeding and menorrhagia in patients with hemophilia A and VWD. Current doses of 4 μg/mL injection or IV have been approved for use in these patient groups (18).

Hormonal options for the management of vaginal bleeding in the nonpregnant patient include combination estrogen–progestin contraceptives (oral, transdermal, or vaginal ring), continuous oral intrauterine or injectable progestins, cyclic progestins or danazol

(oral or vaginal). Selection depends on the need for contraception, coexisting or risk factors for some diseases, and desire for fertility.

Low-dose combined oral contraceptive options are effective for decreasing blood loss by 40% to 50% in some studies. In the emergency setting, combination oral contraciptive pills may be offered in a high-dose fashion when not contraindicated, starting with four pills daily in divided doses for 48 hours then decreasing to three pills daily for 48 hours then two pills daily and then to one pill daily until the pack is complete. This regimen has been shown to be effective in the emergency setting until the patient can follow up as an outpatient.

Progestins work by limiting endometrial growth, inhibiting the synthesis of estrogen receptors, and inhibiting luteinizing hormone. In the emergency setting, megestrol acetate in doses of 40 to 80 mg twice daily has been shown to decrease acute heavy bleeding allowing time for patient to undergo proper evaluation by decreasing blood loss (18). Other regimens include norethindrone 5 mg up to three times daily or medroxyprogesterone acetate 2.5 to 10 mg twice daily to control heavy bleeding. Long-acting progestin only injections have no role in the emergency setting.

Intrauterine progestin-releasing systems are effective in reducing bleeding by 86% in 3 months and 97% at 6 months. These intrauterine systems work by causing the endometrium to become insensitive to ovarian estradiol leading to atrophy of the endometrial glands and suppression of endometrial growth and activity. The effects are reversed by removal of the device. Side effects of intrauterine progestin-containing systems include spotting at irregular intervals, headache, acne, vaginitis, pelvic pain, breast tenderness, and rarely breast tenderness (18).

Danazol is a synthetic steroid with weak androgenic properties. Danazol induces endometrial atrophy relatively quickly by inhibiting estrogen and progesterone receptors (18,23). Minimal, randomized control trial data is available for the use of this agent in the acute setting. Doses of 100 to 200 mg/d have been found to be more effective than other progestins for the control of heavy menstrual bleeding (18,23). Side effects include weight gain,

hirsutism, and acne and counseling patients on expectations is essential for compliance.

CRITICAL INTERVENTIONS

- Resuscitate patients with signs and symptoms of significant blood loss
- Assess pregnancy status as a critical intervention

DISPOSITION

Patients with severe symptoms due to excessive bleeding should be admitted. However, the vast majority of patients are not acutely ill and can be safely discharged home to follow up with a gynecologist or their primary care physician, with or without hormonal therapy. These patients should be evaluated for pregnancy and treatable infections while in the ED.

Patients should be informed of the preliminary nature of the findings and disposition and the need to follow up for further evaluation and care of their symptoms.

Common Pitfalls

- Failure to obtain sexual history from patients in private.
- Failure to refer for further evaluation after the ED evaluation since the exact cause of the bleeding is often not established in the ED.
- Failure to consider medications as possible etiology or contributing cause of the bleeding.

CHAPTER 132 Vaginitis

Ericka L. Powell

Vaginal discharge and discomfort is the most frequent gynecologic complaint of women during their reproductive years. Vaginitis is the inflammation of the vaginal mucosa and vulva that often causes vaginal discharge, irritation, itching, and odor. Vaginal infection may also cause dyspareunia and dysuria. Vaginitis in women aged 14 to 49 is typically due to *Candida, Trichomonas,* and *Gardnerella* species (1). Noninfectious causes include allergies, immune dysfunction, and chemical irritation. Vaginitis after menopause is typically related to atrophy of the vaginal mucosa from decreased estrogen levels.

Evaluation in the emergency department (ED) includes the three "Ps"—pelvic examination, partners (sexual history), and pH combined with microscopic evaluation of the vaginal discharge on wet mount. This approach will yield a diagnosis in the majority of cases. Vaginal cultures have remained the gold standard for diagnosing the cause of vaginitis, although recent developments in point-of-care testing and polymerase chain reaction (PCR) tests may be more sensitive (2,3).

CLINICAL PRESENTATION

The etiology of vaginitis determines the patients' predominant symptoms and clinical presentation. When taking the history, it is important to distinguish changes in the patient's normal physiologic vaginal discharge, which vary with age, pregnancy, use of exogenous hormones, and menstrual cycle.

Candida vulvovaginitis, commonly called a yeast infection, is caused by the fungus *Candida albicans.* These filamentous organisms

penetrate the mucosal surface, causing local tissue lysis and hyperemia. Fungi can be cultured from the vagina in up to 20% of asymptomatic women; they are commensals in the vaginal ecosystem until it is disturbed. Diabetes, immunosuppression (e.g., AIDS or chronic steroid use), and hormonal shifts as occur in pregnancy increase the likelihood of a yeast infection; low-dose oral contraceptives do not (4). *Candida* is typically not associated with other causes of vaginitis: *Trichomoniasis* or *Gardnerella.*

The hallmark complaint of patients with candida vulvovaginitis is vulvar itching and burning associated with dysuria and dyspareunia. Patients complain of a thick white "cottage cheese" discharge that is odorless. The quantity of discharge may vary.

Trichomoniasis is the most common nonviral mediated sexually transmitted disease (STD) in the United States. Non-Hispanic black women are ten times more likely to have this infection. Other risk factors include poverty, lower educational level, and greater number of sexual partners (5,6). *Trichomonas vaginalis,* a unicellular flagellated protozoan, is sexually transmitted and has been isolated in virtually all genitourinary structures of men and women. These protozoa cause urethritis and cervicitis. Trichomoniasis often presents concurrently with bacterial vaginosis (BV), gonorrhea, and other STDs. This infection has also been associated with preterm labor (5).

Patients with trichomonas vaginitis often complain of a thin, copious, malodorous discharge.

BV is the most common cause of vaginal discharge. This infection is diagnosed in 25% of pregnant women and up to 18% women deny recent sexual activity (1). The normal vaginal environment is a dynamic balance of endogenous bacterial flora, including *Lactobacillus,* which helps to maintain a relatively acidic pH of 3.8 to 4.2. Various events may cause the *lactobacilli* to be replaced by high concentrations of anaerobes, particularly *Gardnerella* species, a gram-negative rod. BV is a synergistic polymicrobic infection in which the vaginal flora become primarily anaerobic. This does not produce inflammatory changes; hence the term *bacterial vaginosis* rather than vaginitis.

Women with BV complain of “fishy” vaginal odor and discharge. This odor tends to increase after sexual intercourse when alkaline sperm trigger the release of aromatic amines.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for patients presenting with symptoms of vaginal discharge, itching, or pain includes vaginitis and other infections such as gonorrhea, chlamydia, and herpes. A Bartholin cyst or abscess may present with vaginal pain or itching, and a retained foreign body may present with a malodorous discharge. Less commonly, a rectovaginal fistula or a cervical or uterine neoplasm may present with a chief complaint of vaginal discharge. Various forms of dermatitis may have similar presenting complaints.

ED EVALUATION

Patients with vaginitis can generally be diagnosed and treated based on the ED history, physical examination, wet mount findings, and pH testing. Occasionally, the diagnosis is revealed later on culture results or urinalysis.

In patients with candidiasis, the vulva may appear erythematous, excoriated, and edematous. There may be satellite pustules at the margins of the infection. The vagina may be sore on speculum examination, and a thick white “cottage cheese” discharge may be adherent to the walls of the vagina. The vaginal pH is typically <4.5. This diagnosis is often based on clinical criteria. Diagnostic testing typically requires examining vaginal discharge under a microscope. A small sample of vaginal discharge is placed on a slide with two drops of normal saline and one to two drops of 10% to 20% solution of KOH. This preparation must be scrutinized at multiple power fields to identify the mycelia or pseudohyphae of *Candida,* which have the appearance of tangled branching chains or oval spores (Fig 132.1). The sensitivity of this method varies based on experience, clinical setting, and training when compared to the gold standard yeast culture (3). Although rapid laboratory tests for yeast have been reported to be more sensitive, specific, and cost-effective, these studies are not widely used in the ED (7,8).

Trichomoniasis is characterized by a profuse malodorous “frothy” discharge on physical examination. The discharge is thin and copious and may be grey-yellow or green. Unlike candidiasis, speculum examination reveals inflammation limited to the vaginal walls and the labia minora. Colpitis macularis, “strawberry” cervix, occurs in a small percentage of women, and up to 50% of patients are asymptomatic (9).

Wet mount preparation should be done as soon as possible after collecting a specimen. Trichomonads can be easily distinguished from white blood cells (WBCs) on low-power microscopy (see Fig. 132.1). They are slightly larger than a WBC and show a “corkscrew” motility. It may be difficult to visualize the entire organism if the vaginal smear specimen is cold or undiluted or if the organism is covered by WBCs. In this situation, only the beating flagella are visualized among the WBCs. WBCs on wet mount are a common finding in *Trichomonas* infection, other STDs, and atrophic vaginitis but are not typical of candidiasis or BV. Wet mount examination has a specificity of up to 70% but a relatively low sensitivity. The pH of the discharge is typically elevated, between 5 and 7. *Trichomonas* infection is frequently diagnosed on Pap smear and can also be found on urine samples. PCR testing is not routinely done, and the reported sensitivity and specificity are variable (10,11).

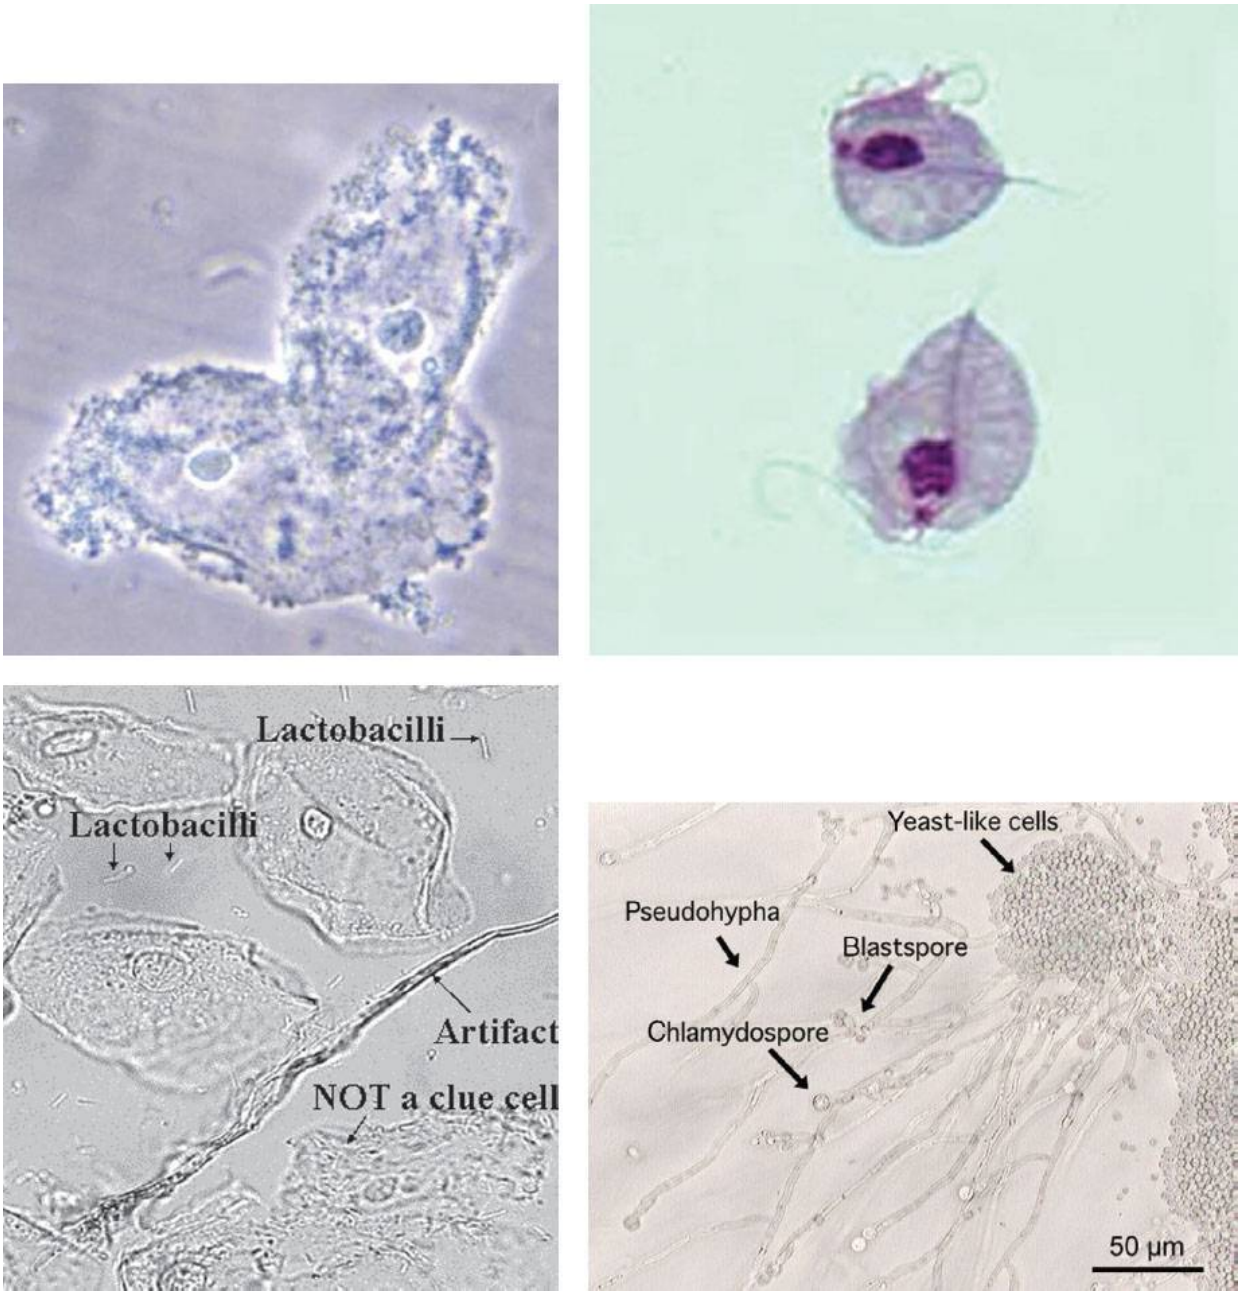

FIGURE 132.1 Wet mount findings in bacterial vaginosis, trichomonas vaginitis, and candida vaginitis.

Patients with BV often have a thin white or grey discharge that is noted on speculum examination to adhere to the vaginal walls. The examiner may notice bubbles in the vaginal discharge. If the cervix is friable or erythematous, the patient should be evaluated for concomitant infections with other STDs. The wet mount microscopic

findings associated with BV have been historically based on Amsel criteria, which include the following:

1. Thin homogenous grey or white discharge
2. Clue cells on microscopy (see Fig. 132.1, bacterial studded vaginal epithelial cells)
3. vaginal fluid pH >4.5
4. positive whiff test (release of fishy amine odor with 10% KOH)

To make the diagnosis of BV, three of the four criteria must be present (12).

An alternative method of diagnosis is Gram stain of a vaginal smear to identify and quantify colonies of anaerobes. The accuracy of diagnosis increases when both tests are used in combination (13). A more rapid BV test with improved sensitivity (BVBlue, Gryphus Diagnostics, LLC, Birmingham, AL) is now available but rarely used. This is a point-of-care chromogenic diagnostic test based on the presence of elevated sialidase enzyme in vaginal fluid samples (14).

KEY TESTING

- Wet mount and pregnancy test
- Vaginal cultures in selected patients

ED MANAGEMENT

Treatment regimens for vaginitis have remained relatively the same over many years. Table 132.1 summarizes the treatment of vaginitis of various etiologies. Recurrence rates for vaginitis are particularly high for *Candida* but also relatively common with *Trichomomas.* Women with resistant infections may need to be referred for additional testing and evaluation for an underlying immunocompromised state. Vaginal culture should be done on all individuals with recurrent vaginitis. Resistant strains of *T. vaginalis* have been reported (15).

TABLE 132.1
Differential Diagnosis and Treatment of Vaginitis

	Candida	Trichomonas	Bacterial Vaginosis
Discharge features	Thick, clumpy white; amount varies	Copious malodorous frothy, homogenous grayish yellow or green	Thin malodorous homogeneous grey or white; moderate amount
pH	<4.5	Between 5 and 7	>4.5
Wet mount	Mycelia, spores/pseudohyphae, WBCs, and epithelial cells[a]	Many WBCs, motile corkscrew trichomonads	Scant WBCs with many clue cells
Whiff test	Negative	Usually positive	Positive
Standard therapy	"Azole" intravaginal cream[b]	Metronidazole 2 g PO single dose or tinidazole 2 g PO single dose	Metronidazole 500 mg PO BID for 7 d or metronidazole gel 0.75%, (5 g) intravaginally for 5 d or clindamycin cream 2%, (5 g) intravaginally at bedtime for 7 d
Alternative therapy	Fluconazole 150 mg PO single dose	Metronidazole 500 mg PO twice daily for 7 d	Metronidazole 2 g PO single dose or clindamycin 300 mg PO twice daily for 7 d
Pregnancy treatment	Clotrimazole 1% 5 g at bedtime intravaginally for 7 d	Clotrimazole 100 mg qhs for 7 d 1st trimester only Metronidazole 2 g oral single dose	Metronidazole 500 mg PO twice daily or 250 mg tid for 7 d or clindamycin 300 mg PO twice daily for 7 d
Partner therapy	None indicated	Metronidazole 2 g oral single dose	None indicated

[a]KOH prep must be used to see fungal elements.
[b]Clotrimazole 1% OTC for 7–14 d, ketoconazole, butoconazole 2% for 3 d.

Candida albicans is typically treated with fungicidal imidazole derivatives. These inexpensive intravaginal preparations are available over the counter and are tolerated by most women. A single oral dose of fluconazole (150 mg) has cure rates similar to those of topical therapies (16). Candidiasis is not sexually transmitted, and partner treatment is not recommended unless males have signs and symptoms of balanitis. Pregnant women should not receive oral fluconazole (5).

T. vaginalis can be cured with single-dose metronidazole (2 g). An alternative treatment regimen consists of metronidazole 500 mg twice daily for 7 days, but compliance is lower. Metronidazole gel is less effective against *T. vaginalis* (<50%) and is not recommended. Tinidazole has been approved by the Food and Drug Administration as an alternative treatment that is very useful for *T. vaginalis* resistant to metronidazole (17). Multiple studies have failed to show teratogenic effects of metronidazole, and symptomatic pregnant patients can be treated with a single oral 2-g dose (10). Patients taking metronidazole should avoid alcohol during treatment and for 24 hours after the last dose to avoid a "disulfiram-like" reaction (18). Patients with an allergy to metronidazole should be referred for desensitization. Other medications such as clotrimazole have higher treatment failure rates. It is imperative to recommend treatment to

all sexual partners of women with diagnosed *Trichomonas*. Reinfection is twice as likely if all partners are not treated. Asymptomatic patients who have positive urine cultures or pap tests should also be treated, as a third of these women can be expected to become symptomatic within 3 months.

Symptomatic patients with BV can be treated with oral and vaginal preparations of metronidazole or clindamycin. All symptomatic pregnant patients should be treated with oral therapy. Intravaginal clindamycin cream has been reported to have adverse effects in pregnancy, including preterm delivery (18). An obstetrician should be consulted on asymptomatic pregnant patients who have diagnosed with BV.

CRITICAL INTERVENTIONS

- Treat infectious causes of vaginitis

DISPOSITION

Patients with simple vaginitis can be treated as outpatients, with follow up by their primary care physician or gynecologist. Those with trichomoniasis should undergo screening for other STDs, along with referral to community resources for counseling regarding safe sex practices and human immunodeficiency virus.

Common Pitfalls

- Failure to perform a thorough history and speculum examination.
- Failure to evaluate for *Candida* and *Trichomonas* in patients complaining of dysuria.
- Neglecting to refer patients for counseling regarding high-risk sexual behaviors and testing for HIV and other STDs.
- Failure to instruct patients to avoid alcohol during a course of metronidazole.
- Failure to recommend treatment for partners of patients with trichomoniasis.

CHAPTER 133 Bartholin Gland Cyst's and Abscess

Flavia Nobay and Ryan P. Bodkin

BARTHOLIN CYST

The Bartholin glands (vestibular glands) sit at the 4 and 8 o'clock positions deep to the labia minora. Their function is to produce moisture for the posterior vestibule of the vagina (1,2). The Bartholin duct is a 2.5-cm structure that connects the glands to the vaginal orifice and is the conduit for these secretions, exiting onto the vestibule at either side of the vaginal orifice inferior to the hymen. The gland begins producing mucus at puberty and starts involution by 30 years of age, therefore cysts and abscesses of this region typically occur in women of childbearing years, most commonly between 20 and 29 years of age. Mucus retention, trauma, infection, inflammation, or physical blockages of the Bartholin ducts are etiologies for cyst and abscess formation and account for 2% of all gynecologic visits per year (1–3).

CLINICAL PRESENTATION

Most Bartholin cysts are asymptomatic and incidentally noted. Patients who present with a Bartholin cyst will complain of unilateral swelling, pressure and discomfort with walking, intercourse, or exercise over the course of days. Typically, a Bartholin cyst or abscess will be seen or felt unilaterally at the posterior vaginal introitus pointing medially (eFig. 133.1). Bartholin cysts are described as feeling soft or fluctuant and are usually well contained. Symptoms are based on the cyst's size with smaller ones being

asymptomatic (1 to 3 cm) and larger ones causing discomfort (4 to 8 cm) (4). A cyst does not need to pre-exist for an abscess to occur. Patient with severe pain or a rapidly expanding mass with intense pressure should raise concern for a Bartholin abscess (5,6). An abscess will have varying degrees of warmth, surrounding edema, and erythema extending into the superior portions of the labia. In some cases, cellulitis extends from the abscess causing more diffuse pelvic pain and low-grade fevers. Systemic illness is infrequently seen unless significant underlying medical illnesses coexist (6).

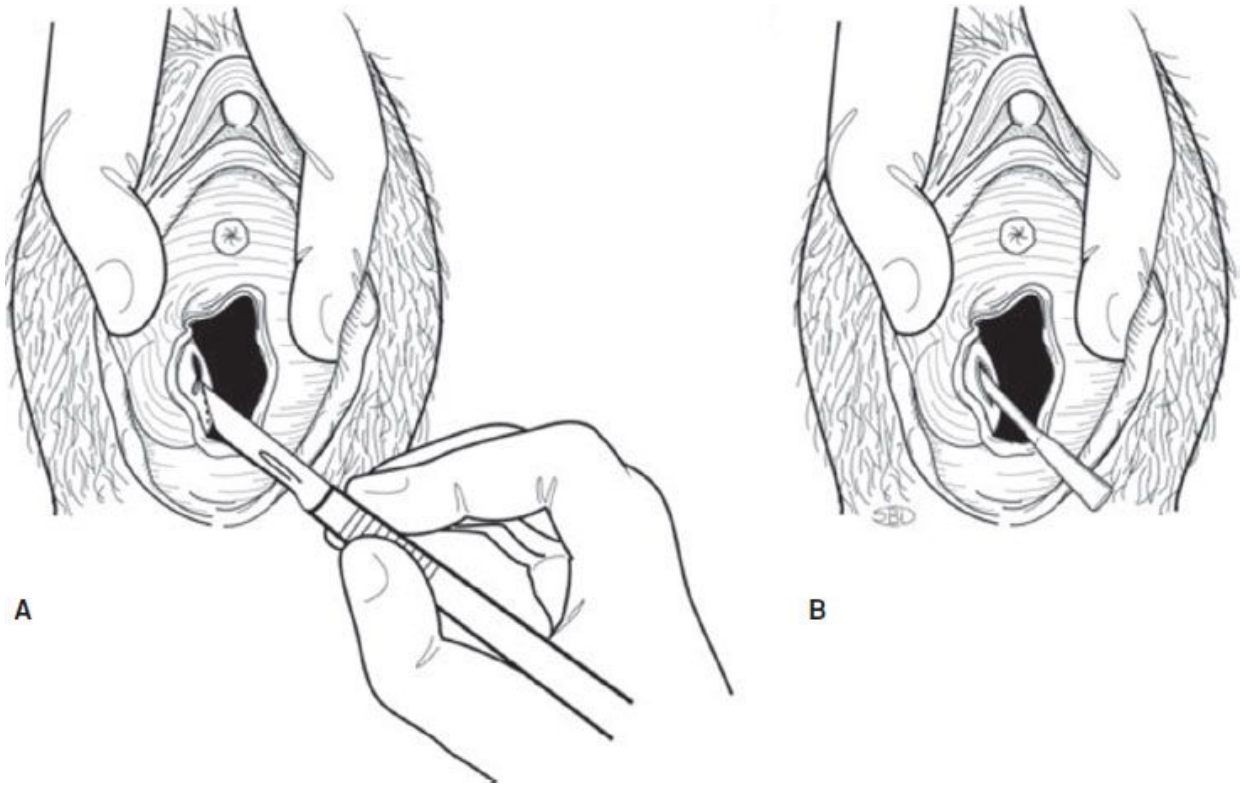

FIGURE 133.1 Treatment options of a Bartholin gland abscess. **A:** Incision and drainage: Make a 0.5 cm vertical incision over the vaginal mucosal side of the labia minora. **B:** Word catheter insertion: Insert the Word catheter as shown, inflate the balloon with approximately 3 mL saline. (From Simon RR, Ross C, Bowman SH, et al. *Cook County Manual of Emergency Procedures*. Philadelphia, PA: Lippincott Williams & Wilkins, 2011.)

eFIGURE 133.1 Abscess of Bartholin gland. © 1992, National Medical Slide Bureau, CMSP.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a tender mass in the vaginal introitus is extensive (Table 133.1). Along with Bartholin cyst/abscess, providers must consider genital warts, herpes, syphilis, hematoma, hidradenoma, lipoma, as well as other varying anatomical cysts (5,6). Women over 40 years old have additional concerns for gynecologic malignancy. Although these diagnoses are rare (incidence of 4% of all gynecologic malignancies), a unilateral vulvar mass is a common clinical presentation for women with vulvar and Bartholin malignancy (7,8). Evidence such as age, time of onset, and systemic symptoms may help differentiate Bartholin and vulvar tumors from nonmalignant masses. Malignancies are described as irregular shaped, firm, fixed, and persistently indurated. Outpatient biopsy of the mass should be considered for any patient over the age of 40 presenting with a first time Bartholin or vulvar mass (8,9).

TABLE 133.1
Differential of Bartholin Cysts or Abscesses

Bartholin gland tumors	Squamous cell carcinoma, adenocarcinoma, adenoid cystic carcinoma, and transitional cell carcinoma
Vulvar masses	Hematoma, fibroma, lipoma
Cysts	Vestibular mucous cysts, inclusion cysts, Gartner duct cysts, Skene duct cysts, canal of Nuck cysts, sebaceous cysts
Sexually transmitted infections	Human papillomavirus, herpes simplex virus
Nonmalignant masses	Leiomyomas, fibromas
Inflammation	Hidradenitis suppurativa
Anatomical abnormalities	Hernias, urethral diverticula

From Boardman LA, Kennedy CM. Benign vulvovaginal disorders. In: Gibbs RS, Karlan BY, Haney AF, et al., eds. *Danforth's Obstetrics and Gynecology*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008:625–647 and Stillman FH, Muto MG. The vulva. In: Ryan KJ, Berkowitz RS, Barbieri RL, eds. *Kistner's Gynecology: Principles and Practice*. 6th ed. St. Louis, MO: Mosby; 1995:66–68.

ED EVALUATION

Patients with Bartholin duct cysts and abscesses require a careful history and physical examination. A complete history will include time of onset and duration of illness, systemic symptoms, a sexual history, and a gynecologic history including documentation of previous vulvar abnormalities. The physical examination should include visual and digital inspections of the external genitalia. If a vaginal discharge is present, a pelvic examination with appropriate cultures for sexually transmitted infections should be obtained.

Routine imaging and blood tests are not required for a Bartholin cyst. Cultures are helpful in understanding the changing microbiologic landscape of Bartholin abscesses. Bartholin cysts are generally considered sterile and abscesses are considered to be polymicrobial (10,11). The previous association of Bartholin abscesses with sexually transmitted infections has decreased from approximately one-third of isolates to less than a fifth of isolates (8% to 16%) with *Neisseria gonorrhoeae* and *Chlamydia trachomatis* as the primary causative agents (12). Escherichia coli, *Bacteroides fragilis* and Methicillin-resistant *Staphylococcus aureus* (MRSA) are increasingly isolated from Bartholin abscesses (13–15). Pregnancy testing should be obtained on all patients of childbearing age.

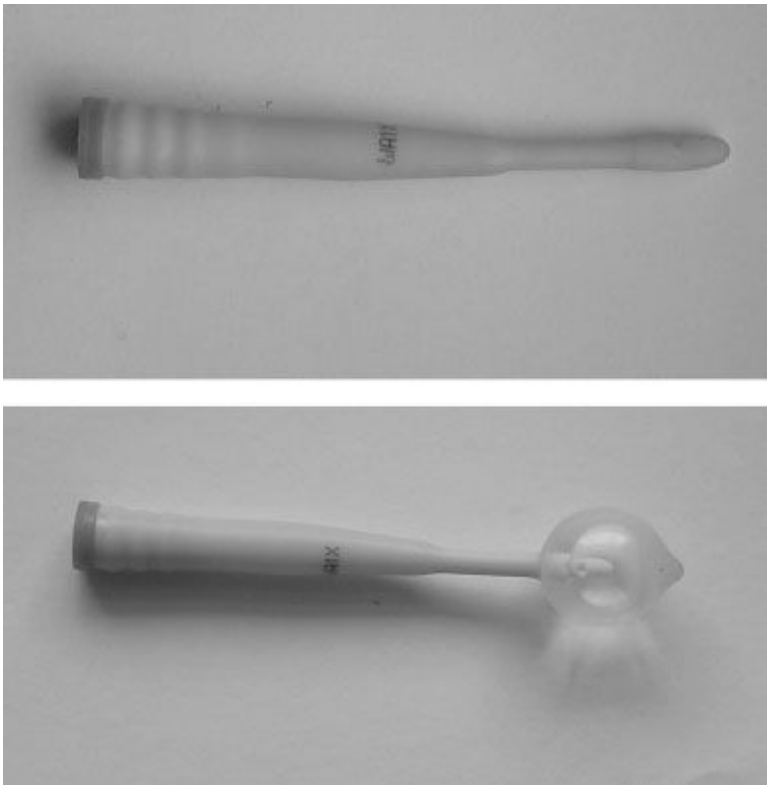
KEY TESTING

- Routine testing and imaging are not helpful in most cases

ED MANAGEMENT

An asymptomatic, small Bartholin cyst should be conservatively managed without antibiotics. Similarly, small cysts that are minimally uncomfortable may be referred to an outpatient gynecologist for treatment. Abscesses that have already ruptured require only analgesia and local care with Sitz baths and warm compresses (4).

Cysts that are large enough to cause significant discomfort and Bartholin abscesses should be incised and drained in the ED. Most incision and drainage (I + D) procedures can be performed under local anesthesia with the aid of oral or intravenous pain medications. If a fistula tract is created, this procedure can lower the currently cited rate of recurrence of a Bartholin cyst or abscess of up to 17% (16). Inserting a Word catheter or Vaseline gauze for 4 to 6 weeks at the time of I + D allows for epithelization of the cyst or abscess cavity creating the desired tract. The Word catheter is a latex catheter with a balloon tip, which is filled with 3 mL of saline after insertion (eFig. 133.2).



eFIGURE 133.2 Word catheter before and after instillation of 3 cc sterile water. (From Fleisher GR, Ludwig S, Henretig FM, et al. Textbook of Pediatric Emergency Medicine. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

Local anesthesia, and incision of the abscess or cyst should be on the mucosal surface of the labia minora (eFig. 133.3). The small vertical incision/puncture made with a no.11 scalpel blade should lie parallel but external to the hymenal ring at the 5 or 7 o'clock position. Incisions of the skin surface of the labia minora can result in increased complications. The incision (0.5 to 1 cm) should be large enough to allow for pus to be expelled and the Word catheter or gauze to be inserted but not fall out (Fig. 133.1). Tucking the catheter into the vagina after insertion increases patient comfort (17). In an effort to decrease recurrence rates and comfort for the patient, new therapies have been suggested for treatment in the ED, however no large studies have been performed to validate efficacy (18).

eFIGURE 133.3 The Bartholin gland abscess should be approached from the mucosal surface for local anesthesia, aspiration, or incision and drainage. (From Kovac SR. Advances in Reconstructive Vaginal Surgery. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.)

Bartholin cysts or localized abscesses that are properly drained do not require antibiotics. If a patient is at high risk for a sexually transmitted infection, CDC guidelines for antibiotics treatment should be started after culture of the abscess (http://www.cdc.gov/sTD/treatment/2010) (19). Women who are at risk of complicated infections (immunocompromised, presence of cellulitis, or systemic signs of infection) should be treated with broad-spectrum antibiotic that includes MRSA coverage for 1 week (2,20).

DISPOSITION

All patient should be referred to a gynecologist for close follow up. Patients with recurrent abscesses, cysts, age greater than 40, or patients with concerning signs of symptoms for malignancy will need more urgent referral to an outpatient gynecologist. Sitz baths, pelvic care, warm compresses, and oral pain medication can increase patient comfort. Outpatient antibiotics are dependent on the clinical scenario. Patients should refrain from vigorous exercise or vaginal

intercourse while the catheter is in place to prevent expulsion. If the Word catheter or packing falls out prematurely, it can be reinserted in the ED or referred to the gynecologist.

Common Pitfalls

- Moderate sized Bartholin cysts only require I + D if symptomatic, Bartholin abscesses should be drained regardless of size.
- Bartholin cysts do not require antibiotics, only selected populations with Bartholin abscesses require antibiotics.
- The incision for the I + D should be made on the mucosal surface as opposed to the skin side of the vaginal introitus.
- Confirm the patient's allergies before placing the latex-based Word catheter.

CHAPTER 134

Breast Masses and Infections

Minal Amin and John M. Howell

Effective ED evaluation of a breast mass depends on recognition of two major processes: Cancer and infection. Mastitis and breast abscesses usually occur in lactating women, but may also represent inflammatory carcinoma in the elderly (3,6,9). Cancer, on the other hand, may present in a manner similar to that of fulminant mastitis (6,9). Mastalgia, a palpable breast mass, and nipple discharge represent common complaints in patients seeking medical attention (6). Hence, initial evaluation of a breast mass may be difficult, challenging, and highly relevant to ultimate patient outcome.

CLINICAL PRESENTATION

Approximately 80% of breast lesions are benign and present as smooth, movable, and discrete masses with regular margins (Table 134.1). Fibrocystic changes (FCCs) and fibroadenomas (FAs) are the most common and second most common benign breast disorders in women (2,4).

TABLE 134.1
Physical Findings Suggestive of Benign and Malignant Breast Masses

Benign	Malignant
Soft or firm on palpation	Firm or hard on palpation
Discrete, regular margins	Indistinct margins
No attachments, mobile	Attached to skin or deep fascia, fixed
More likely to be tender	Less likely to be tender
No discharge	Bloody discharge
No skin changes	Dimpling of skin, nipple retraction

Cancerous lesions are hard with distinct edges that are serrated and irregular. Skin changes range from none to local edema or frank ulceration (3,5,7). Fibrosis may shorten the Cooper ligament and cause skin dimpling, a process also seen in fat necrosis (5,7). Bloody nipple discharge suggests ductal carcinoma (8). More commonly, it may reflect the presence of a solitary benign intraductal papilloma (7). Lymph nodes involved in the spread of breast cancer are initially rubbery and shotty. Ultimately, they harden with progressive infiltration. The axillary ipsilateral node glands are most commonly involved followed by the internal mammary and supraclavicular sites (5,7).

Erythema, edema, tenderness, and induration are late skin changes in the setting of breast cancer, but they are commonly seen in lactation mastitis typically 1 to 3 months postpartum (4,6,7). Chronic, relapsing nonpuerperal infection can develop in the subareolar ducts. This is known as periductal mastitis or duct ectasia and has been linked to diabetes and smoking (5). Fluctuance is the hallmark of a superficial abscess. Fluctuance may not be apparent if deep intramammary and retromammary loculations are present in the breast musculature (Fig. 134.1) (10). A “peau d’orange” appearance characterized by diffuse erythema and edema, mastitis, or abscess in a nonlactating woman should serve as a warning sign of inflammatory cancer (3,6,7,9).

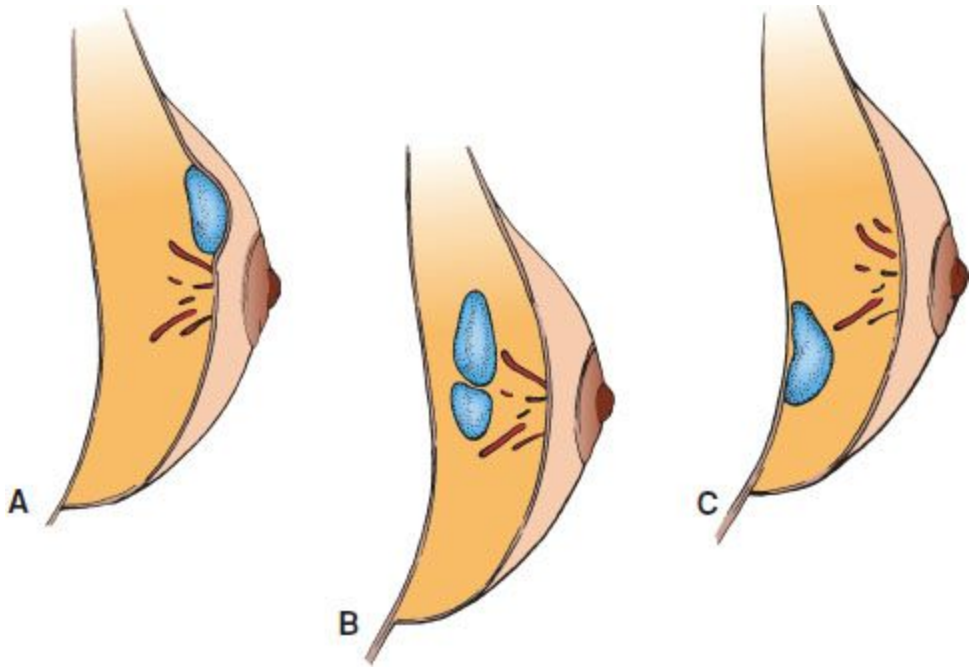

FIGURE 134.1 Breast abscesses. **A:** Superficial abscess. **B:** Intramammary abscess. **C:** Retromammary abscess.

Postmenopausal breast abscesses are commonly subareolar, often presenting with pain and erythema. They are occasionally associated with chronic fistulas from the subareolar ducts to the periarolar skin (5). Expressing pus from the nipple or areola can identify a mammillary fistula. Nipple retraction and inversion are also seen (5). Although rare, recurring subareolar abscess (Zuska disease) is a bacterial infection of the breast that is characterized by a triad of draining cutaneous fistula from the subareolar tissue; a chronic thick, pasty discharge from the nipple; and a history of multiple, recurrent mammary abscesses (4).

Breast bud enlargement occurs in the first 1 to 2 weeks of life in 60% of neonates. These enlarged breast buds may become infected, usually with either *Staphylococcus aureus* or *Escherichia coli.* The clinical presentation is either simple cellulitis or abscess (8).

Paget disease of the nipple reflects carcinoma of the mammary ducts underlying the nipple areola complex. It represents 2% to 4% of breast malignancies. Initially, it appears as an eczematoid rash

and then progresses to chronic skin inflammation with a surface crust. It can be confused with benign breast disease (5,11).

DIFFERENTIAL DIAGNOSIS

Cancer

One in eight women in the United States develops breast cancer. An estimated 234,580 new cases of breast cancer in women and 2,240 in men will be diagnosed in 2013 (1). It is the leading cause of death in women between the ages of 44 to 50. Yearly, approximately 40,000 women die of breast cancer (1,2). Seventy percent to 80% of women diagnosed with breast cancer will have no family history. Primary risk factors for breast cancer are age greater than 50 and being female (1,2). Risk factors for breast cancer are listed in Table 134.2. Absolute risk is listed in Table 134.3. In women who are younger than 25 years of age, fewer than 5% of breast masses are malignant. The incidence of breast cancer rises significantly during childbearing years. By the age of 70, more than 75% of breast masses are malignant (12). Discussions of breast cancer histopathology and staging are beyond the scope of this chapter and are contained elsewhere (2,7).

TABLE 134.2
Risk Factors and Relative Risk of Breast Cancer

Risk Factors	Estimated Relative Risk
Advanced age >60	>4
Family history	
• Ovarian cancer in women <50 yrs	>5
• One first-degree relative	>2
• Two or more first-degree relatives	>2
Personal history	
• Personal history	3–4
• + BRCA1/BRCA2 mutation	>4
• Breast biopsy with atypical hyperplasia	4–5
• Breast biopsy with LCIS or DCIS	8–10
Reproductive history	
• Early age at menarche <12 yrs	2
• Late age of menopause	1.5–2
• Late age of first-term pregnancy (>30 yrs)/ nulliparity	2
Use of combined estrogen/progesterone HRT	1.5–2
Current or recent use of oral contraceptives	1.25
Lifestyle factors	
• Adult weight gain	1.5–2
• Sedentary lifestyle	1.3–1.5
• Alcohol consumption	1.5

LCIS, lobular carcinoma in situ; DCIS, ductal carcinoma in situ; HRT, hormone replacement therapy.

TABLE 134.3
Absolute Risk of Breast Cancer in American Women by Age

Current Age	Absolute Risk of Developing Breast Cancer in Next 10 yrs (%)
20	1 in 1,681 (0.06)
30	1 in 232 (0.4)
40	1 in 69 (1.4)
50	1 in 42 (2.4)
60	1 in 29 (3.4)
70	1 in 27 (3.7)
Lifetime risk	1 in 8 (12.4)

From American Cancer Society, Breast Cancer Facts & Figures 2011–2012 and Cancer Facts & Figures 2013.

Benign Neoplasms

FCCs, formerly called fibrocystic disease, comprise the most frequent benign disorder of the breast (4). They are noncancerous changes in breast tissue. They cause mastalgia, tenderness, and nodules to arise in one or both breasts prior to menses in women between 20 and 50 years of age (4). Fibrocystic breast changes are classified proliferative or nonproliferative (up to 70% of biopsies) (4). Proliferative changes are associated with ductal hyperplasia and must be followed longitudinally as there is a four- to fivefold increase in breast cancer in these women (2).

FAs are the second most common benign neoplasms of the breast (2,4). They occur most commonly in younger women between the ages of 15 and 35 and are considered a disease of early reproductive life. They are nontender, well defined, spherical, firm, and highly mobile. In most cases, FAs are managed conservatively as they do not increase the risk of breast cancer. Women who are older have complex FAsor a family history of breast cancer have a higher incidence of cancer (4).

Lipomas are superficial and occur in any quadrant of the breast. They are benign tumors composed of mature fat cells and are well defined, smooth, lobulated, and nontender. It may be clinically difficult to distinguish lipomas from other conditions, thus causing diagnostic and therapeutic challenges (4).

Mondor Disease

Mondor disease is thrombosis of the superior epigastric, thoracoepigastric, or lateral thoracic veins as they traverse the breast. It is characterized by the sudden appearance of a red tender and palpable cord. The cord subsequently becomes a fibrous band associated with tension and skin retraction. Although Mondor disease is self-limited and usually diagnosed with ease (13,14), emergency physicians must be aware of its existence to properly diagnose it and to rule out the presence of systemic disorders, especially breast cancer (13,14).

Idiopathic Granulomatous Mastitis

Idiopathic granulomatous mastitis (IGM) is a rare inflammatory breast disease of unknown etiology. The clinical presentation can mimic an abscess, infectious mastitis, or mammary carcinoma and can be misdiagnosed as cancer. IGM is associated with women who are parous and have a history of oral contraceptive use. Glucocorticoid therapy, resection, and methotrexate are treatment options (15,16). The recurrence rate has been reported as 5% to 50% in the literature (17).

Mastitis and Abscess

Infectious complications may be seen in up to 10% of lactating women (18). Lactation mastitis occurs in 2% to 3% of women and breast abscess between 5% to 11% of women with mastitis (19). A postpartum breast abscess is caused by normal skin pathogens that invade through cracks in the nipple (2,4,10). Staphylococci are the most common causative agents (2,4). Streptococci are cultured less often (8). Preventive measures include nipple hygiene (cleaning), hand washing, cleansing of the infant's skin, and early recognition (8).

Postmenopausal breast abscesses are distinct from puerperal forms in cause and presentation. Approximately 90% are subareolar. They often arise from mixed infections that include aerobic and anaerobic flora (5). They are associated with ductal ectasia, a chronic inflammation of major ducts below the nipple and areola. Recurrence rates after simple incision and drainage exceed 39% (3). Mammillary fistulas occasionally form between the areola and infected lactating glands (8,9).

Fat necrosis may present as a tender lump in the breast, typically as a result of trauma in 50% of cases (2,3,4). It is a benign, nonsupportive inflammatory process of the adipose tissue. The mass usually does not enlarge but may be ill-defined, spiculated, and associated with skin retraction. It is a mimic of breast cancer (2,3,4).

ED EVALUATION

Evaluation in the emergency department (ED) hinges upon the information gathered during the history and physical examination. As noted previously, many features including the size, location, tenderness, skin changes, and rapidity of onset help in narrowing the differential. The important distinction is cancer versus infection. Patients with a mass suspicious for cancer usually require no further ED evaluation but need expeditious outpatient referral. Patients with signs or symptoms of metastatic cancer should have further ED evaluation including laboratory and imaging studies to search for complications and the extent of spread. Ultrasound may be helpful in diagnosing a breast abscess if the clinician is uncertain. Sonographic evidence suggestive of a breast abscess includes a hypoechoic rim and adjacent interstitial fluid (20,22).

KEY TESTING

- Consider ultrasound if abscess is suspected

ED MANAGEMENT

Simple mastitis in the lactating woman, without abscess formation, is treated with antimicrobials that are effective against staphylococci and streptococci (2,5). Cephalexin (250 to 500 mg four times a day), dicloxacillin (250 to 500 mg four times a day), or erythromycin (250 to 500 mg four times a day) in penicillin-allergic patients is appropriate. Breastfeeding should be encouraged with manual pumping, if needed, along with local heat and empiric antibiotic therapy (2,4,5). Simple nonlactating breast infections should be treated with amoxicillin–clavulanic acid at 875 mg twice a day (3,5).

Superficial abscesses can be treated in the ED. Ultrasound-guided needle aspiration is emerging as a treatment of choice for most breast abscesses. It causes less scarring and does not require general anesthesia. Repeated aspiration and oral antibiotics may be necessary (8,10).

Neonatal breast bud infections should be treated with parenteral antibiotics (e.g., ampicillin 50 mg/kg and cefotaxime 50 mg/kg) after cultures of the blood and urine. Incision and drainage may be necessary and should be performed peripherally to avoid cosmetic complications (21).

CRITICAL INTERVENTIONS

- Refer all patients with a suspicious breast mass for expeditious outpatient evaluation.
- Drain superficial breast abscesses, with ultrasound guidance as needed.

DISPOSITION

Women suspected of having breast cancer should be referred immediately to a consultant who is experienced in the diagnosis and management of breast disorders. Outpatient arrangements for mammography with subspecialist referral should be made for all patients who are not pregnant and at least 20 years old. As there is an appreciable rate of false-negative mammography (3,19), patients should be counseled that a negative study does not invariably mean absence of disease.

Mastitis may be difficult to distinguish clinically from cellulitis, abscesses, or inflammatory cancer. Patients should be closely followed within 24 hours. Mammillary fistulas should be referred to a surgeon for excision and definitive closure (8–11). Postmenopausal abscesses also necessitate surgical consultation due to high recurrence rates after drainage (3,8–10,22).

Patients with suspicious breast masses need not be admitted unless they have advanced disease or complications on presentation, intractable pain, or important psychosocial issues necessitating admission. In general, the initial evaluation of suspicious breast masses is done on an outpatient basis.

Women with mastitis who are toxic-appearing should be admitted and placed on intravenous antibiotics. Women with simple

infections that do not improve or that worsen after 24 hours should also be admitted.

Consider transfer or referral when no physician experienced in the management of breast disorders is available. Patients must be stable and have no evidence of septic shock. Antibiotics and pain control should be initiated prior to transfer.

Common Pitfalls

- Inflammatory cancer may present with erythema, edema, and tenderness. Infection in a nonlactating breast and failure of postpartum mastitis to resolve in a timely manner should suggest the possibility of cancer.
- Inadequate drainage of a breast abscess may lead to chronic infection with substantial morbidity and cosmetic deformity.
- Misdiagnosis of a deep breast abscess as mastitis.

CHAPTER 135

Sexual Assault

Carolyn Sachs

Emergency physicians, more than any other medical professionals, provide care for violently injured and abused patients. With victims of sexual assault in particular, emergency physicians must be attentive to the physical, emotional, and judicial needs of the patient. The legal definition of *sexual assault* varies by state and country. In general, sexual assault denotes any physical act of sexual contact without legal consent (1). Perpetrators of sexual assault may use physical force to overcome the victim's lack of consent, but this is not required. Lack of voluntary consent for sexual contact because of intimidation, threats, or incapacitation equally fulfills the definition of sexual assault (2). Rape is a subset of sexual assault, which involves nonconsensual genital, anal, or oral penetration (3).

The National Crime Victimization Survey, a random-digit dial telephone survey collects data yearly on nonfatal violent crimes against males and females 12 years of age and older, reported a steady decrease in the number of sexual assaults estimated yearly over the last 20 years. The most recent data available (2011) from this survey show an incidence of 243,805 sexual assaults per year, down from 898,239 in 1993. However, even survey methodology undercounts assault as it does not sample those populations without a home telephone who are more likely to be victimized and still suffer from low disclosure rates due to shame and fear (4).

This chapter provides information for the emergency practitioner needing to treat and examine the sexually assaulted patient in the absence of immediate access to a specialized sexual assault provider program.

Male victims of sexual assault also require appropriate care and treatments. Although this chapter does not provide a separate discussion pertaining to the male victim, much of what is discussed has applicability to both male and female victims. For a discussion of pediatric sexual abuse, see Chapter 292.

CLINICAL PRESENTATION

Sexually assaulted patients may present immediately to the emergency department (ED) or be brought to the ED by law enforcement personnel. In either case, the ED staff should be aware of the guiding principle of providing compassionate and confidential treatment in a timely fashion. A victim may be accompanied by friends or family, who should be allowed to stay with the victim in accordance with her wishes. If the victim presents alone, staff should offer her the chance to call a companion or a rape crisis advocate to remain with her during the ED stay.

ED EVALUATION

Physicians must first treat any life- or limb-threatening physical injury. A minority of sexually assaulted patients will require such immediate intervention, but in the rare case of coexistent severe trauma, care should be taken not to destroy or alter evidence on the patient's body if possible. Some states mandate physicians to notify law enforcement when treating a sexually assaulted patient. Emergency physicians must be familiar with their own state laws regarding reporting. Even when reporting is mandatory, patients may elect not to talk with police (5).

In the ED, the patient should be placed into a private room. Physicians should use a compassionate tone to explain the procedure of the examination and forensic evaluation and to obtain written informed consent for these. Obtaining this consent carries important psychological implications after a sexual assault in which a victim was denied this right. If the hospital has an arrangement with a special sexual assault team, that team should become involved as early as possible. An increasing number of institutions

have sexual assault nurse examiner (SANE) programs, which provide highly specialized treatment for sexual assault victims (6).

The ED evaluation begins with an appropriately tailored history rather than an exhaustive account of the details of the encounter. Recounting sexual violence can be very traumatic. The history should include information necessary for medical treatment, to complete any standardized state forms, and for the collection of evidence. This information may be important when trying to correlate physical findings or corroborating evidence. eTable 135.1 lists the many elements of the history that law enforcement personnel may request for historical forensic documentation.

TABLE 135.1
Single-Dose Therapy for Preventing Sexually Transmitted Disease after Sexual Assault

Medication	Dose
Prevention of Gonorrhea (GC)	
Ceftriaxone	250 mg IM (recommended by CDC)
or	
Cefixime	400 mg PO (second line if ceftriaxone not available)
or	
Azithromyacin	2,000 mg PO (also active against chlamyida)
Prevention of Chlamydia	
Azithromyacin	1,000 mg
Prevention of Trichomonas and Bacterial Vaginosis	
Metronidazole	2,000 mg (optional)

eTABLE 135.1
Important Elements in the Sexual Assault History

- Time, date, and place of assault if known
- Type of force or coercion if used (e.g., weapons, held down, restraints)
- Threats (e.g., "threatened to hurt my parents if I resisted")
- Number and description of assailants
- Use of alcohol or drugs by patient (voluntary or forced)
- Lapses in consciousness (due to trauma or toxins including "date rape" drugs)
- Type of assaultive contact (kissing, licking, fondling, or penetration of mouth, breasts, body, genitals, and/or anus)
- Condom use
- Perpetrator ejaculation and location (to guide specimen collection)
- Postassault activities such as bathing, urinating, defecating, gargling, eating, brushing teeth, genital wiping or washing, douching
- Pre-existing injuries, genital infections, or abnormalities that may alter the expected appearance
- Recent voluntary intercourse (within 5–7 d of assault)
- Pertinent past medical history (medications, medication allergies, tetanus and hepatitis B immunization status, HIV status if known, current method of birth control, last menses)

A pertinent gynecologic history should include gravity, parity, last menstrual period, contraceptive history, recent intercourse besides the current assault, history of recent sexually transmitted disease (STD), and any gynecologic surgery. If the victim is on an oral contraceptive, she should be asked if she has missed taking any pills. All of this information will assist in deciding what type of medical treatment is necessary.

Before beginning the physical examination, the physician should be sure the patient understands that she is in control of every element of the examination and may refuse at any point. The objectives of the physical examination are to determine the need for medical treatment, to gather specimens for analysis, and to document observations that may be used to corroborate the victim's account. Law enforcement may want to take photographs before she undresses. Gloved hands must be used to collect clothing after the victim disrobes while standing on a clean sheet. Clothes must be placed into paper rather than plastic bags, as plastic restricts air circulation and may lead to fungal or bacterial growth that can degrade biological evidence.

Examiners should inspect skin for scratches, lacerations, abrasions, contusions, or bite marks. The mouth should be examined for injury, with special attention to the inner lip and palate, where

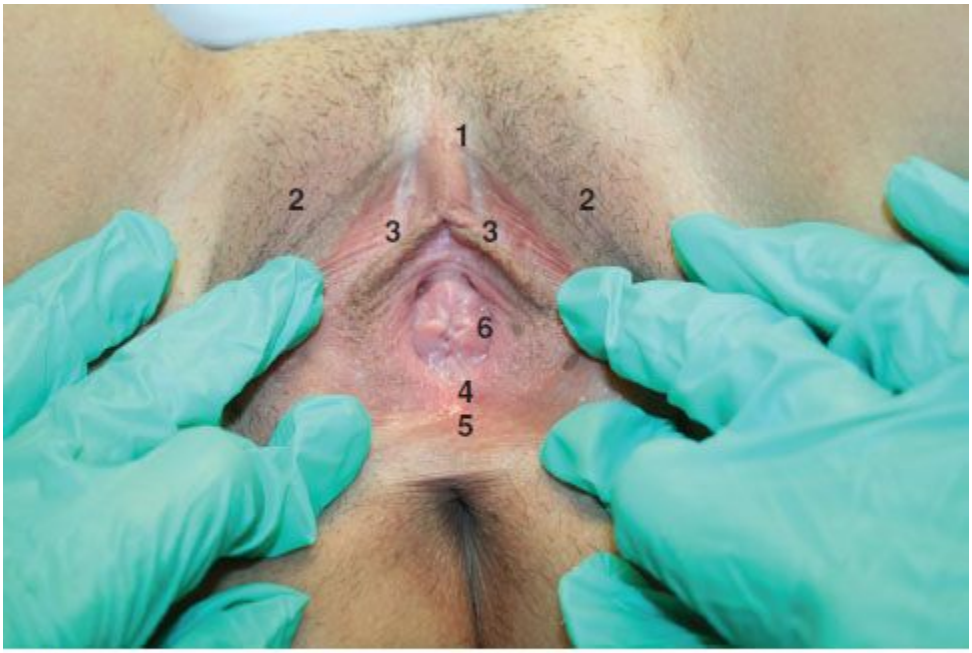
direct trauma often leaves abrasions and contusions. If the patient reports oral sexual contact within the previous 12 hours, buccal swabs should be collected for potential evidence by running them between the buccal mucosa and teeth. The local crime laboratory may also request a buccal swab to be used as a reference sample of the victim's DNA. In addition to documentation of body trauma, any foreign material, such as hair, blood, or semen, should be noted and collected.

If relevant, examiners may collect foreign material from under the fingernails, or alternatively trim the nails over a clean piece of paper. Any material obtained should be bundled with the paper and placed in an appropriate envelope. Examination of the skin may reveal lightly crusted areas that are suspicious for semen. These should be collected with a swab moistened with saline or water. A Woods lamp may help to identify these areas because semen fluoresces under ultraviolet light; however, other substances also fluoresce, so this test is nonspecific (7).

The external genitalia should be checked for trauma and evidence of semen, which should be swabbed as previously described. If it is present on pubic hair, the matted hairs should be trimmed and collected. In patients with pubic hair, this hair may be combed to find strands of the assailant's hair. Examiners should place a clean piece of paper below the patient's buttocks and comb through the hair onto the paper. Hairs, comb, and paper are then folded up and placed in evidence collection bags. Some crime laboratories request plucked pubic hairs for victim reference. However, these hairs are rarely needed because DNA from the victim is obtained from blood or buccal cells, and hair can be provided later (8).

The physician should describe the location, shape, and color of any genital injury using proper anatomic terms. Figure 135.1 shows the female genital areas most likely to display injury after rape (posterior forchette, hymen, labia minora). If photographs are taken, it is often helpful to highlight injury with the use of toluidine blue dye, although this may be considered an advanced technique and not readily available in most EDs. A small amount of the blue dye can be applied to the perineum at the area of suspected injury and

the excess wiped off with a lubricant-moistened cotton ball or gauze. Injured areas often display linear blue stain, because the dye is taken up by the nuclei of exposed submucosal cells. Labial separation and traction can assist examiners in viewing the perineum and hymen. Examiners should attempt to inspect the entire perimeter of the hymen using a swab or a Foley catheter inserted through the hymenal orifice and inflated (9). Examiners may use magnification to enhance identification of injury.



1. Clitoris
2. Labia majora
3. Labia minora
4. Fossa navicularis
5. Posterior fourchette
6. Hymen

FIGURE 135.1 Female genital anatomy. (Used with permission and state no reproduction or use without the explicit written consent of Malinda Wheeler, RN, FNP, SANE-A, SANE-P, Founder and Director of Forensic Nurse Specialists.)

The vaginal wall should be inspected for injury after gentle insertion of a speculum lubricated only with warm water. Pooled secretions in the posterior fornix should be aspirated and placed in a sterile receptacle or collected with sterile swabs. Some areas request vaginal washings, obtained by instillation and aspiration of 5 to 10 mL of nonbacteriostatic sterile saline solution. Although the Centers

for Disease Control (CDC) recommend culturing for gonorrhea and chlamydia during the speculum examination, this step may be omitted in patients who have received appropriate prophylactic antibiotics (10).

A bimanual examination is not a routine part of the sexual assault examination. The anal area should be examined for injury in all victims. If the patient has anal pain, reports anal penetration, or has experienced a lapse in consciousness, anoscopy should be performed to look for internal anal and rectal injury. Anal and/or rectal swabs should be obtained. Anoscopically visible injury may be found even when the external anal examination is normal; this may be especially important in male victims (11).

All swabs need to be thoroughly air dried, packaged, and labeled with the patient's information, the name of the examiner, the date, and site. Examiners may choose to prepare a wet mount of the vaginal or rectal swabs to detect motile and nonmotile sperm. Motile sperm are not usually found after 12 hours. Most ED sexual assault examiners omit this step because of lack of formal training. Criminal laboratories may identify nonmotile sperm in vaginal secretions 72 hours or longer after intercourse and in a cervical sample up to 3 weeks after intercourse (12).

Law enforcement personnel may request samples of the victim's blood for DNA reference and for drug and alcohol testing. Testing may also be indicated for hepatitis B, hepatitis C, human immunodeficiency virus (HIV), and syphilis serologies. Urine pregnancy testing should be performed because this may affect the choice of pharmacologic treatment.

The findings on the history and physical examination and complete information concerning collected specimens should be documented thoroughly at the time of the examination.

KEY TESTING

- Detailed, standardized forensic examination when indicated

ED MANAGEMENT

The ED treatment of the sexually assaulted patient includes psychosocial support, treatment of physical injuries, pregnancy prevention, and prevention of STDs.

Psychosocial support begins with the first individual responsible for patient contact. All staff must be sensitive and maintain strict patient confidentiality, and prior arrangements should be made with social work or a rape crisis volunteer to provide immediate support and assistance with the evaluation procedure.

Medical treatment of traumatic injuries suffered during the assault does not differ from routine treatment, but it should be performed in a way that does not compromise potential evidence, if possible. For example, if the patient requires urinary catheterization, external genital swabs should be collected prior to the preparatory precatheter cleansing, and bite wounds should be swabbed for evidence prior to irrigation.

Pregnancy prevention, or "emergency contraception," should be offered to all patients of childbearing age. Levonorgestrel (1.5 mg), known commercially as "Plan B One-Step," has proven exceedingly safe and is currently available in the United States without a prescription. It is effective for up to 5 days after intercourse and has not been associated with teratogenicity if the patient becomes pregnant from the rape or other intercourse in the preceding 7 days (13).

The risk of contracting an STD as the result of sexual assault has been estimated to be 5% to 10%, and varies according to geographic area and assault characteristics. Thus, prophylaxis should be offered to all victims. The most frequently diagnosed infections among women who have been sexually assaulted are gonorrhea, chlamydia, trichomoniasis, and bacterial vaginosis (14).

Current treatment recommendations (Table 135.1) include ceftriaxone 250 mg IM for the prevention of gonorrhea, and single-dose azithromycin (1 g) to prevent chlamydial infection (10). The need to prevent trichomoniasis and bacterial vaginosis is less urgent, and the treatment (metronidazole) may cause abdominal pain and vomiting in some individuals.

Hepatitis B virus vaccine should be given to unimmunized or inadequately immunized patients (10). Hepatitis B immune globulin should be reserved for high-risk exposures involving a known hepatitis B–positive assailant.

Victims may be particularly concerned about the transmission of HIV. The risk of transmission of HIV from one episode of unprotected receptive vaginal intercourse with an infected individual is approximately 1 in 1,000. The estimated risk with unprotected receptive anal intercourse is between 8 and 32 in 1,000 (15). However, the risk may be higher in sexual assault victims as a result of tissue injury. Unfortunately, there is no evidence that postexposure prophylaxis (PEP) after sexual exposure prevents infection (16). If considered, PEP should be given as soon as possible and is not indicated more than 72 hours after exposure (Table 135.2). The CDC recommends PEP only for HIV-negative victims with vaginal, anal, or oral penetration by a perpetrator *known to be HIV-positive,* and they make no recommendation in other sexual assault scenarios (14). The risks and side effects of antiretroviral therapy must be discussed with the patient. Repeat HIV-antibody testing is recommended approximately 2 to 3 months after the assault.

TABLE 135.2
Postexposure Prophylaxis of HIV for Adults Including Lactating Women and Adolescents >40 kg

Drug	Strength/ Form	Dose	Duration
Zidovudine (AZT) and	300 mg tablet	1 tablet every 12 hrs	28 d
Lamivudine (3TC)	150 mg tablet	1 tablet every 12 hrs	28 d

CRITICAL INTERVENTIONS

- Provide immediate psychosocial support during the ED evaluation.

- Assess and treat for serious physical injuries.
- Offer prophylaxis for pregnancy and sexually transmitted diseases.

DISPOSITION

Admission to the hospital may be required in the case of significant physical trauma. in addition, ED practitioners may need to consult with a surgical specialist (gynecologist, urologist, or general surgeon) for significant vaginal, penile, or anal trauma that requires surgical care.

Sexual assault may trigger severe depression and even suicidality. Emergency physicians should assess each patient for suicidality and take appropriate steps to assure timely intervention with a mental health professional, if necessary. In most areas in the United States, rape crisis advocates can provide timely support to victims during the examination and in follow-up. The importance of planned psychological follow-up from the ED cannot be overemphasized. Survivors may suffer from rape trauma syndrome (RTS), a pattern of symptoms similar to posttraumatic stress disorder (PTSD) (17). The patient should be reevaluated approximately 1 to 2 weeks after the initial medical evaluation to determine the need for further counseling. It is advisable for a member of the medical team (e.g., a social worker) to contact the victim after discharge to address any concerns and to encourage appropriate follow-up care.

The sexual assault victim may be discharged from the ED in the company of relatives or friends. Follow-up care must be arranged before discharge. This should include medical follow-up with a primary care physician or gynecologist at 2 weeks and 6 weeks after the assault to reevaluate for pregnancy and STDs.

Common Pitfalls

- Failure to appropriately collect, transfer, and document specimens, with an appropriate chain of evidence.
- Failure to be familiar with requirements and protocols that may vary with the institution and state.

• Failure to offer prophylactic therapy for pregnancy and STDs.

CHAPTER 136

First-Trimester Vaginal Bleeding

Pamela L. Dyne

Vaginal bleeding (VB) in early pregnancy is a very common emergency department (ED) complaint. The differential diagnosis is relatively short, with ectopic pregnancy being the most serious, and threatened miscarriage being the most common. An understanding of the definitions, classifications, and management options is important for efficient management in the ED and effective communication with consultants. Septic spontaneous miscarriage and gestational trophoblastic disease (GTD) (molar pregnancy) are also discussed in this chapter.

CLINICAL PRESENTATION

The patient's clinical history can be instrumental in making diagnoses in most disease processes, and early pregnancy bleeding is no different. Although many patients presenting to the ED with VB know if they are pregnant, many do not. In one multicenter study involving several different types of EDs, 63% of women who thought they were pregnant were correct. However, 7% who said there was no chance they could be pregnant and 10% of those reporting a normal last menstrual period (LMP), were in fact pregnant (1). Another more recent study in a suburban University hospital suggests 100% negative predictive value of a woman stating that pregnancy was impossible (2). Therefore, a negative history for pregnancy may or may not be completely reliable,

depending on the patient population. Approximately 20% of all pregnancies are complicated by first-trimester VB, and about 50% of them will end in spontaneous abortion (3).

DIFFERENTIAL DIAGNOSIS

Table 136.1 defines the spectrum of spontaneous miscarriages, with their clinical, laboratory, and ultrasound findings. In virtually all cases of bleeding in the first 20 weeks of pregnancy, a careful investigation utilizing history and physical examination, β human chorionic gonadotropin (β-hCG) levels, and transvaginal ultrasound can establish either the correct diagnosis or a logical management plan that will safely lead to a correct diagnosis. If the bleeding is experienced around the time of or just after the expected normal menses, *implantation bleeding* should be considered. This is a fairly common occurrence with a benign physiologic cause. As the embryo burrows into the highly vascular decidual tissue, blood escapes into the uterine cavity and out through the cervix. It ranges from a pinkish discoloration of the vaginal discharge to bleeding equivalent to that of a menstrual period. It can last 1 or 2 days but usually not longer. Most commonly, it occurs in the fifth or sixth week after the LMP and women may mistake this bleeding for a normal menses, making it a common cause of inaccurate dating of gestational age.

TABLE 136.1
Spontaneous Abortions

Term	Clinical	US Findings
Threatened abortion	Vaginal bleeding (VB) or abdominal pain, os closed	Embryo with cardiac activity, or empty gestational sac (5–6.5 wks), empty uterus (3–5 wks), or subchorionic hemorrhage with any of the above
Complete abortion	VB, benign examination, os closed, falling β-hCG	Empty uterus
Incomplete abortion	VB, benign or tender examination, os open or closed, slowly falling or plateau β-hCG	Thickened, irregular endometrium (>5 mm double stripe)
Abortion in progress/ inevitable abortion	VB, os open	Gestational sac in process of expulsion
Embryonic demise (missed abortion)	Varied, os closed	Embryo lacking cardiac activity with CRL >5 mm
Blighted ovum (anembryonic gestation, embryonic failure)	Varied, os open or closed	Gestational sac too big to not have embryo (>20 mm)
Septic abortion	Varied, os open or closed, abdominal tenderness, peritoneal signs, CMT, foul cervical discharge	Thickened, irregular endometrium (>5 mm double stripe)

β-hCG, beta human chorionic gonadotrophin; CRL, crown-rump length; CMT, cervical motion tenderness.

Septic spontaneous miscarriage is another clinically important cause of VB. Fortunately, the estimated fatality rate from septic spontaneous miscarriage is very low, ranging from 0.4 to 0.6 per 100,000 spontaneous miscarriages. Patients may also present with complications of induced abortion, and this is discussed in detail in Chapter 139.

GTD, also known as *molar pregnancy,* is an abnormal proliferation of the trophoblastic cells. Frequently, GTD presents with abnormal bleeding mimicking an incomplete or threatened miscarriage. Other signs are passage of hydropic villi (that tend to have a grapelike

appearance) through the vagina. Uterine size may be larger (50%) or smaller (25%) than the estimated gestational age, and there may be enlarged cystic ovaries resulting from theca-lutein cysts. The β-hCG level is usually higher than expected for gestational age (generally greater than 100,000 mIU/mL). Common patient complaints include severe nausea or vomiting, and less commonly, there may be signs of preeclampsia or hyperthyroidism. The definitive diagnosis is made by histologic evaluation of the tissue, which is frequently not done until after surgical evacuation. GTD is more commonly seen in those of Asian descent, those who had a prior molar pregnancy, and first pregnancies in the early or late years of childbearing (<15 or >35 years old). In the general population, the incidence is 1 in 1,000, although it may be as high as 1% in the Asian population. The condition is usually benign; however, at the more serious end of the spectrum of GTD is choriocarcinoma, a frankly malignant lesion that is usually responsive to chemotherapy. If GTD is suspected, the uterus should be evacuated as soon as possible, although this is not an emergency unless signs of preeclampsia or hemodynamic instability are present. Nevertheless, the patient should be seen by an obstetrician-gynecologist within the next 24 hours so that definitive therapy can be arranged. Prior to discharge from the ED, the thyroid status should be evaluated so that therapy for secondary hyperthyroidism can be initiated prior to any operative intervention.

In addition to the pregnancy-related etiologies discussed previously, bleeding may be caused by lesions entirely unrelated to the pregnancy, such as structural or infectious lesions on the cervix or vagina, or from the urinary or gastrointestinal (GI) tract. Table 136.2 summarizes these nonpregnancy-related causes of VB that may occur in pregnancy.

TABLE 136.2
Nonpregnancy-Related Causes of Vaginal Bleeding

Diagnosis	History and Physical Findings	Diagnostic/ Confirmatory Tests
Nephrolithiasis	Varied, abdominal pain, hematuria	Renal ultrasound, cath UA
Cystitis	Varied, abdominal pain, hematuria	Cath UA
Lower GI tract bleeding	Varied, BRBPR, hemorrhoids	Hemoccult testing, physical examination
Cervical cancer	Vaginal discharge, cervical lesion	Cervical biopsy (not recommended for in ED or during pregnancy)
Cervicitis or bacterial vaginosis	Varied, abnormal discharge, pain, spotting	Wet prep, cervical cultures
Cervical ectropion	Postcoital bleeding, friable columnar epithelium seen on endocervical canal	Physical examination
Cervical polyps	Pinkish buds protruding from cervical os	Physical examination
Vaginal wall trauma, foreign body, or neoplasm	Varied	Physical examination

UA, urinalysis; BRBPR, bright red blood per rectum.

ED EVALUATION

The initial focus of the ED evaluation of a woman with first-trimester VB is on ruling out ectopic pregnancy (see Chapter 137). Once ectopic pregnancy has been excluded, the task is to further classify the type of bleeding. This is done through a synthesis of the history and physical examination, laboratory and ultrasound information, and serial assessments.

The history obtained in the ED should include the quantity of VB, passage of clots or tissue, and evolution of symptoms. The amount and character of the bleeding has been shown to help differentiate between threatened abortion and miscarriage (4). Symptoms consistent with urinary tract infection (UTI) or uterine infection should be elicited. The physical examination begins with assessment of the vital signs with prompt intervention if they are suggestive of hemodynamic compromise. Evaluation for tenderness at the costovertebral angles, abdomen, and suprapubic area should be

performed. Traditionally the physical examination should include a speculum and bimanual pelvic examination, with specific attention paid to the evaluation of the status of the internal cervical os and assessment of the degree of uterine and adnexal tenderness. Multiparous patients will often have a soft and slightly dilated external os, but it is the internal os that must dilate in order for passage of products of conception (POC) to occur. Often the cervix has a conical shape, with the internal os as the point of the cone. If the examining finger is able to *gently* pass through the end-point of the cone, the internal os is open. If the examining finger is not able to *gently* penetrate the point of the cone, the internal os is closed. One should not aggressively force a finger or any instrument through the internal os to determine its integrity. To do so can cause injury to the cervix, and theoretically cause a miscarriage. The uterus should not be tender unless POC are retained or are passing through the cervix at that time.

In a 2009 review, Isoardi took the position that routine pelvic examination is not supported by the literature. She concluded that the pelvic examination does not provide additional diagnostic information over transvaginal ultrasonography used in conjunction with quantitative β-hCG. However, she noted that a pelvic examination should be performed when ultrasonography and quantitative β-hCG testing are unavailable or the results inconclusive, and in those presenting with severe bleeding, since the removal of endocervical products can be an important resuscitative measure (5). The argument in favor of routine pelvic examination is to detect an open os or POC, or to find other causes of bleeding such as cervical polyps or lesions.

There are several laboratory tests that are helpful in the evaluation and management of ED patients with VB in early pregnancy. They include a urine pregnancy test, a urinalysis, blood type and Rh, complete blood count (CBC), and serum quantitative β-hCG. A thorough understanding of the indications and utility of these tests is important for proper interpretation of their results.

The urine pregnancy test is 99.4% sensitive for diagnosing pregnancy at approximately the same time as the woman misses her

period, or when the serum β-hCG level is greater than 25 mIU/mL. False negatives occur when the serum β-hCG is between 10 and 50 mIU/mL, and when the urine is dilute (<1.015 specific gravity). The urine pregnancy test quickly establishes the pregnancy status and should be a routine order for patients with VB, regardless of the menstrual history (6).

A urinalysis should be ordered in all pregnant VB patients to diagnose UTI, regardless of symptoms. UTI is a risk factor for miscarriage. Asymptomatic bacteriuria and pyuria are relatively common in pregnancy, occurring in 2% to 11% of pregnant women. Up to one-fourth of these asymptomatic women go on to develop upper tract infections (7). Thus it is important to screen for and treat UTI in pregnant patients to potentially prevent miscarriage.

Routine screening for Rh status in the pregnant patient with VB has been controversial. The American College of Emergency Physicians Clinical Policy subcommittee recently reviewed this topic and concluded that while there is sufficient high-quality literature to support the administration of 50 μg of Rh(D) immune globulin to Rh-negative women who have documented first-trimester loss of an established pregnancy to prevent Rh alloimmunization, there is insufficient evidence either for or against its use in threatened miscarriage or ectopic pregnancy (8). However, it has become a common practice to give Rh immune prophylaxis to Rh-negative pregnant women with VB.

A CBC may be helpful in estimating the amount of blood loss, or to serve as a baseline for subsequent visits. The *quantitative* β *human chorionic gonadotropin,* or β-hCG, is a measure of trophoblastic tissue activity, which is a marker for the volume of living trophoblastic tissue and a function of renal clearance. Both ectopic and intrauterine pregnancies (IUPs) produce β-hCG, although they usually differ in the rate at which the quantitative β-hCG level increases. Patients with ectopic pregnancy or an abnormal IUP both tend to have a lower quantitative β-hCG level than those with viable IUPs at a given gestational age (6,9). Because of the large range of β-hCG for each stage of embryonic development, a single value of β-hCG is not useful for differentiating among normal IUP, abnormal

IUP, and ectopic pregnancy. However, the rate of rise in the β-hCG level can be quite helpful. Initial work by Kadar et al. on subjects with symptomatic first-trimester pregnancies resulted in the often-quoted "β-hCG doubling time" of early gestations, namely a 66% rise in 2 days. For normal gestations, the β-hCG peaks at about 100,000 at about 10 weeks EGA, and then falls to a steady state of about 20,000 to 50,000 for the duration of pregnancy (10). More recently Barnhart et al. studied 287 symptomatic first-trimester pregnancy patients over 5 days from presentation of their symptoms, and found that the median rise of β-hCG was 1.5 times after 1 day (50% increase), and 2.24 after 2 days (124% rise). The smallest increase for a normal viable IUP was 24% at 1 day and 53% at 2 days (11). Given this variability, it is important to interpret serial hCG data carefully. Furthermore, a "normal" rise in β-hCG does not eliminate the possibility of miscarriage or ectopic pregnancy, and such diagnoses should be established definitively using methods such as ultrasonography (12).

The primary value of *pelvic ultrasonography* in the evaluation of a pregnant VB patient is to confirm the presence of an IUP, which ostensibly rules out ectopic pregnancy. Ultrasound is also useful in evaluating the prognosis for a threatened gestation because there are sonographic findings consistent with normal gestational development at various levels of β-hCG. The hormones of pregnancy cause an early uterine decidual reaction that may be seen on ultrasound soon after a missed menses, but this is nonspecific and occurs with both IUP and ectopic pregnancy. The earliest sonographic landmark of an IUP is the gestational sac. With endovaginal ultrasound, this can be visualized at between 30 and 33 days gestational age.(13). The gestational sac typically lies eccentrically within the decidua of the endometrium, and may be seen to have two sonographically distinct layers which are referred to as the double sac sign (DSS) (Fig. 136.1) or an intradesidual sign (IDS), and is what radiologists have historically used to define findings consistent with an IUP. Recent literature has shown that there is poor interexaminer agreement regarding the presence of these signs. Therefore a round or oval intrauterine fluid collection in

a woman with positive β-hCG should be considered to be an IUP, regardless of the presence or absence of a DSS or IDS (14). The yolk sac seen within the gestational sac is the next sonographic landmark of the developing pregnancy and is seen between 34 and 38 days after the LMP. The embryo and cardiac activity are seen concurrently and reliably adjacent to the yolk sac between 39 and 43 days gestation by endovaginal ultrasound (13). Table 136.3 lists the sonographic findings of early pregnancy development with their corresponding discriminatory levels of β-hCG and gestational ages.

TABLE 136.3
Sonoembryology of Early Pregnancy

Sonographic Landmarks of Early Pregnancy	EGA (wks)	Serum Quantitative β-hCG (mIU/mL)
Gestational sac	4.5	500–1,000
Yolk sac	5.5	1,000–7,500
Embryo with cardiac activity	6.5	5,000–23,000

EGA, estimated gestational age; β-hCG, β human chorionic gonadotropin.

FIGURE 136.1 Transvaginal ultrasound of a gestational sac, showing the "double ring."

The sonographic finding that is most reassuring for a favorable prognosis is the presence of normal fetal heart rate (FHR). Dede et al. found that for patients with first-trimester VB who had slow FHR detected by pelvic ultrasound (<130) had a predictive value of 92.6% for spontaneous fetal loss before 20 weeks gestation. Another sonographic finding that correlates with a poor outcome is a shorter than normal cervical length (<40 mm), which was found to be 80.8% sensitive and 54.7% specific for fetal loss before 20 weeks gestation (15). The effects of a subchorionic hematoma, gestational age, and maternal age together on gestational prognosis have been investigated. A subchorionic hematoma greater than two-thirds the circumference of the chorion had a twofold increase in the rate of spontaneous abortion (19%) compared to those with a smaller hematoma (9%). In addition, the spontaneous abortion rate for women over age 35 was twice that for younger women, 14% versus 7%, respectively (16).

Molar pregnancy has a characteristic but unusual pattern on ultrasound that is referred to as a *snowstorm pattern* (Fig. 136.2).

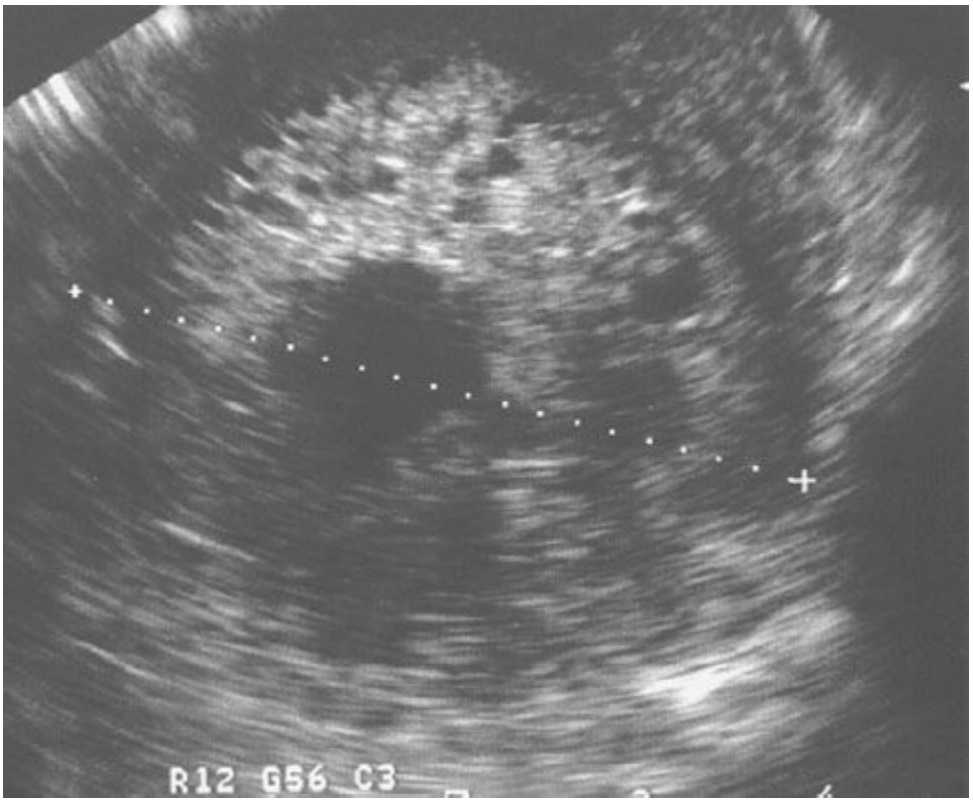

FIGURE 136.2 Transvaginal ultrasound of a molar pregnancy, with typical "snowstorm" appearance.

KEY TESTING

- Serum quantitative β-hCG, urinalysis, type and Rh
- Pelvic ultrasound

ED MANAGEMENT

The first consideration in management of a first-trimester patient who has VB is hemodynamic status. A patient who is bleeding heavily and hemodynamically compromised should be resuscitated with intravenous fluids. Obtain type-specific blood for transfusion if the patient's hemodynamic status does not respond to 2 L of crystalloid. Gynecology should be consulted immediately as the hemodyamically compromised patient will most likely need either an emergency dilation and curettage (D&C) if there is evidence of intrauterine POC, or emergency laparoscopic surgery for presumptively ruptured ectopic pregnancy. Early bedside ultrasound

is critical in the unstable patient to determine whether there is an IUP or free fluid. Bedside sonography by emergency physicians is highly accurate in the determination of IUP compared to that performed by radiology (17).

It may also be necessary to remove POC in the open cervical os by *gentle* traction with a ring forceps, thereby completing a spontaneous miscarriage. If more than gentle traction is required, there may be incomplete separation of tissue from the endometrium. In that case, it is advised to not simply pull harder, as mechanical separation can result in severe hemorrhage; rather, obtain gynecologic consultation for assistance. When this tissue is completely removed, a rapid decrease in bleeding and pain should follow. If ultrasound does not suggest further retained POC, the patient should be observed for a few hours to ensure continued clinical resolution of bleeding and cramping, as well as the internal cervical os at least beginning to close. Such patients usually can be discharged with gynecologic follow-up. Patients who continue to have heavy bleeding, pain, tenderness, or a persistently open internal cervical os are presumed to have retained POC and should receive gynecologic consultation for possible D&C.

For patients diagnosed in the ED with a nonviable gestation, be it an embryonic demise (aka blighted ovum), an incomplete miscarriage (aka retained POC), or early fetal demise (aka missed miscarriage), there are three different possible management strategies: expectant, surgical, and medical. Expectant management allows time for the spontaneous passage of the POC. Surgical management is usually by D&C. Medical management uses an antiprogesterone medication, usually misoprostol, to aid in the expulsion of POC. A 600- or 800-μg tablet-form dose of misoprostol may be administered orally or intravaginally on day 1, and a second dosage may be self-administered by the patient on day 3, if clinically indicated. Studies suggest that both dosages and routes of administration have equal efficacy, with an overall success rate of 71% to 92%. The addition of pretreatment with oral mifepristone does not improve on the success rate of misoprostol alone (18). Patients with incomplete miscarriage who have had bleeding within

the previous 24 hours have the best success rate (87% to 92% successful), and those with embryonic failure or fetal demise who have not had recent bleeding tend to have less success with medical management (71% to 77% successful) (19).

Trinder et al. studied 1,200 women in a randomized controlled trial of the three management strategies of miscarriage. All three strategies had a low incidence of uterine infection (2% to 3%). Upon follow-up at 10 to 14 days, ultrasound evidence of retained POC was present in 10%, 36%, and 20% of the surgical curettage, expectant, and medical management groups, respectively, and the mean duration of bleeding was 8, 12, and 11 days, respectively. All groups returned to daily activity in about 2 days (20). Other smaller studies have also shown better success rates for medical management over expectant management, with the most significant difference in those with early fetal demise (9). Therefore, it seems reasonable to offer all three management strategies to women, and allow participation in the decision (21,22). Patient satisfaction varies greatly across management strategies (23).

Septic spontaneous miscarriage is a polymicrobial infection and should be treated immediately with broad-spectrum intravenous antibiotics, evacuation of the uterus and admission. In addition, blood and cervical discharge should be obtained for culture. Disseminated intravascular coagulation is sometimes seen in this setting, either as a result of prolonged retention of fetal tissue caused by release of necrotic tissue into the bloodstream or in women who have developed frank septic shock.

It is a common practice to give Rh immune prophylaxis to Rh-negative pregnant women with VB as described above (8). If the gestation is less than 12 weeks, a dose of 50 μg is sufficient. However, as pregnancy dating is difficult and inaccurate, some recommend that all unsensitized Rh-negative women with VB receive 300 μg of Rh immune globulin in the first or second trimester. This should be given before the patient leaves the ED, but protection occurs if it is administered within 72 hours of bleeding. It is not necessary to repeat the dosage at subsequent visits for subsequent bleeding before 20 weeks of gestation. Another 300-μg

dose should be administered in the third trimester or prior to delivery.

CRITICAL INTERVENTIONS

- Aggressively resuscitate unstable patients with suspected ectopic pregnancy and obtain early gynecologic consultation.
- Administer broad-spectrum antibiotics to patients with suspected septic spontaneous miscarriage or infected retained POC.
- Obtain gynecologic consultation for women diagnosed with miscarriage in the ED to decide on a management strategy, be it D&C, expectant, or medical management with misoprostol.

DISPOSITION

Patients who are hemodynamically stable, appear nontoxic, are not in pain or bleeding heavily, and have reliable access to gynecology follow-up may be sent home. If a patient is known to not have an ectopic pregnancy, then once the result of the urinalysis and Rh screen have been interpreted and the patient treated accordingly, the patient with either threatened or completed spontaneous miscarriage may have routine (1 to 2 week) gynecologic follow-up. These patients often need serial β-hCG measurements, and it should be determined prior to discharge where this should occur. There is no evidence that reduction in activity or medical therapy will affect the outcome of the threatened miscarriage. Despite this, rest is often prescribed for social and psychological reasons. It is important to emphasize to a patient and her partner that normal pregnancies tolerate normal physical activity. Patients with miscarriage will be dispositioned per the recommendations of the consulting gynecologist, as discussed above.

All patients who are discharged from the ED should be encouraged to return immediately if they develop worrisome symptoms such as fever, intolerable pain, or symptoms consistent with severe anemia. Most importantly, all patients with VB should be reassured that the cause of their bleeding and/or miscarriage is not their fault and that there is nothing they can do to prevent

miscarrying an abnormal pregnancy. Patients and family members may have many misconceptions about this, and correct information can be very important to the psychological well-being of these patients. The emotional response to a spontaneous miscarriage is variable, from relief to overwhelming grief. A sensitive approach to these families is a critical part of treatment and is often the most significant effect a clinician can have. Offering referral to professional counseling or support groups should be a routine part of managing these women, and preprinted discharge instructions with appropriate referral phone numbers may be very useful.

Common Pitfalls

- Failure to consider ectopic pregnancy in the first trimester of pregnancy.
- Underestimating the amount of blood loss. Because these patients tend to be healthy young women, they can maintain nearly normal vital signs despite large volume losses, until abrupt decompensation occurs.
- Failure to give antibiotics early in the course of a suspected septic spontaneous miscarriage.

CHAPTER 137
Ectopic Pregnancy

G. Richard Braen and Richard S. Krause

A leading cause of maternal morbidity and mortality in the United States is ectopic pregnancy. It is also a major factor in decreasing the future fertility of the affected woman. Unfortunately, the frequency of ectopic pregnancies in the United States has increased by fivefold since 1970 (1). Pooled data indicate that the current incidence of ectopic pregnancy is about 19 per 1,000 pregnancies (2% of all pregnancies in women in the United States will be ectopic) (2). Furthermore, it is estimated that of 100 women with a history of ectopic pregnancy, approximately 50% will be infertile, 35% to 40% will subsequently have a successful pregnancy, and 10% to 15% will experience a second ectopic pregnancy (3).

Ectopic pregnancy is the result of implantation of a fertilized ovum at a site other than the endometrium of the uterine cavity (4). The most frequent site of implantation is the lateral two-third of the fallopian tube (80%) (Fig. 137.1). About 15% implant is in the medial one-third. Interstitial or cornual implantation occurs in approximately 3% of ectopic gestations. Interstitial and abdominal implantations carry the greatest risk of mortality because of their hemorrhagic tendencies (5). Extratubal ectopic gestations occur in about 5% of cases: in the ovary (3%), within the abdominal cavity (2%), or in the cervix (rare). Interstitial pregnancies (where the fertilized egg implants in the intrauterine portion of the fallopian tube) occur in $<3\%$ of tubal pregnancies (6). Combined intrauterine and extrauterine gestations (*heterotopic pregnancy*) were formerly very rare, with an estimated incidence of 1 in 30,000 pregnancies (7). Combined pregnancies are now estimated to occur in up to 1 in

3,000 normal patients and 1 in 100 patients being treated with assisted reproductive technologies (8), particularly if the woman had previously received clomiphene citrate (9).

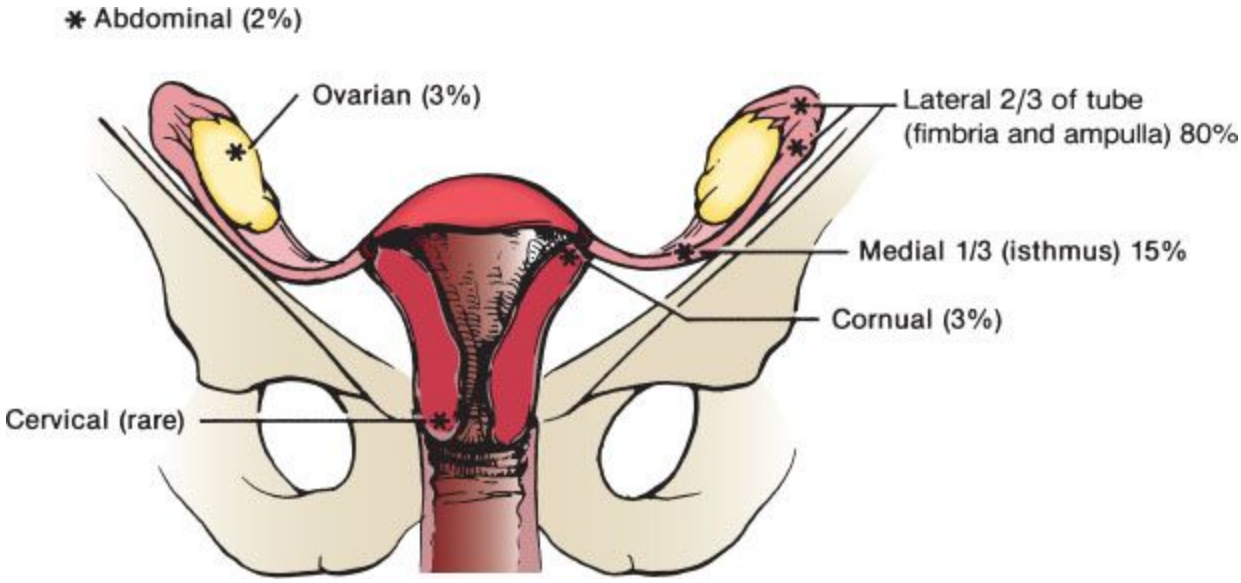

FIGURE 137.1 Sites of implantation in ectopic pregnancy.

The most common predisposing factors include intrinsic or extrinsic abnormalities of the fallopian tube and abnormal development of the embryo itself. Abnormalities of the fallopian tube are the most important cause of ectopic pregnancy. The most common source of tubal pathology is pelvic inflammatory disease (PID). The risk of ectopic pregnancy is known to be several times more likely among women with a history of salpingitis (7). All pathogens, including *Chlamydia* and *Neisseria gonorrhoeae,* are believed to cause tubal distortion and scarring, which adversely affect tubal patency and motility. Subacute infection with less virulent organisms may actually increase the amount of residual tubal pathology because diagnosis and treatment may be delayed.

There are multiple risk factors for developing an ectopic pregnancy. However, up to 42% of women with ectopic pregnancy have no risk factors (10). Table 137.1 lists several important population characteristics. Increasing age at the time of conception is a risk factor for developing an ectopic pregnancy. The risk of

ectopic pregnancy is threefold greater in older patients than in younger (11).

TABLE 137.1
Rates of Ectopic Pregnancy for Various Population Subgroups

Population Characteristic	Ectopic Pregnancies as a Percentage of Total Pregnancies in Each Population Group (%)
Overall	0.94
Age (yrs)	
15–19	0.45
20–29	0.82
30–39	1.42
Contraception	
Oral contraceptives	0
Barrier	0.002
Intrauterine device	14
One or more episodes of salpingitis	6.9
Prior tubal sterilization	16
Prior ectopic pregnancy	11.2

Adapted from Weström L, Bengtsson LP, Mårdh PA. Incidence, trends, and risks of ectopic pregnancy in a population of women. *Br Med J (Clin Res Ed)*. 1981;282:15–18.

Fourteen percent of all pregnancies in women with an intrauterine device (IUD) are ectopic. The IUD does not prevent ovulation, as does the oral contraceptive, but interferes with intrauterine implantation of the ovum. Therefore, a woman wearing an IUD is potentially at risk for tubal implantation if her ovum becomes fertilized. Additionally, IUD wearers are frequently subjected to delayed diagnosis of ectopic pregnancy. Health care providers may confuse the symptoms caused by an ectopic pregnancy with those related to the mechanical or inflammatory response to an IUD and fail to consider the possibility of an ectopic gestation.

Ectopic pregnancy must be considered after tubal sterilization procedures. Sixteen percent of women who become pregnant after tubal sterilization have an ectopic gestation. This probably

represents partial recanalization, allowing access of the sperm to the ovum, but impaired passage of the fertilized ovum to the uterine cavity. Like IUD wearers, patients who have had prior tubal sterilization are frequently subjected to a delay in diagnosis.

Women who have had an elective abortion within the preceding 2 weeks and who present with symptoms referable to the genital tract are at risk of having an undiagnosed ectopic pregnancy. Confirmation of products of conception in the pathology specimen is necessary to exclude the diagnosis of ectopic pregnancy. This is a frequent problem in large urban clinics with a high incidence of therapeutic abortions performed with unreliable follow-up (12). Although many of the features discussed increase the risk of ectopic pregnancy, no combination of risk factors confirm or exclude the diagnosis with a high degree of certainty (13).

The major life-threatening condition associated with an ectopic pregnancy is intra-abdominal hemorrhage with shock, causing approximately 85% of fatalities from ectopic pregnancy. Misdiagnosis contributes to half of the fatalities (5).

CLINICAL PRESENTATION

Any female with lower abdominal pain or vaginal bleeding with a positive pregnancy test should be suspected of having an ectopic pregnancy. The “classic” triad of amenorrhea, vaginal bleeding, and abdominal pain is neither sensitive nor specific for ectopic pregnancy. Of patients with ectopic pregnancies, approximately 15% present with this classic picture, and of patients with the classic constellation of signs and symptoms, only 14% actually have an ectopic gestation (14).

Abdominal pain is the most common symptom and is reported in more than 97% of patients. Abnormal vaginal bleeding is present in 55% to 86% of cases (12,15). A “normal” menstrual history is obtained in 15% to 30% of patients, and abdominal pain occurs *without* bleeding in up to one-third of patients. It should be emphasized that consideration of an ectopic pregnancy is based on a history of abdominal pain and a positive pregnancy test in the first

trimester. The quality, character, and location of the pain are highly variable. It may be cramping, colicky, steady, or dull. Flank or lower back pain may be noted, or tenesmus may occur from rectal irritation caused by blood in the cul-de-sac. The pain may be localized to either lower quadrant or may be generalized, suggesting hemoperitoneum. Profuse vaginal hemorrhage occurs in the minority of cases and suggests rupture of a cornual implantation. Between 6% and 16% of patients who present to an ED with first trimester bleeding will ultimately be found to have an ectopic pregnancy.

Vital signs are typically normal, except in those patients with significant blood loss. This will be manifested by orthostatic hypotension, tachycardia, or shock. Paradoxical bradycardia may be seen. Any woman of childbearing age who presents with signs of hemorrhagic shock without historical or physical evidence of trauma has a ruptured ectopic pregnancy until proven otherwise.

Tenderness on pelvic examination is the most common sign and is present in 83% to 97% of cases (12,15). The physical findings depend on whether intraperitoneal irritation has occurred from leakage or rupture of the ectopic gestation. A palpable mass may represent the ectopic gestation or may be felt on the side opposite the ectopic gestation, possibly representing a corpus luteum cyst rather than the ectopic pregnancy itself.

Patients with ectopic pregnancy are more likely to have moderate-to-severe sharp abdominal pain with abdominal or pelvic tenderness and a small uterus on physical examination. Peritoneal signs are uncommon but highly predictive of ectopic pregnancy. However, no constellation of findings (by either history or physical examination) can confirm or exclude the diagnosis of ectopic pregnancy with a high degree of reliability (13).

DIFFERENTIAL DIAGNOSIS

Given the broad spectrum of patient complaints and physical findings, the differential diagnosis of ectopic pregnancy is proportionally broad. The most common pelvic conditions that

share clinical aspects of ectopic pregnancy include PID, threatened or incomplete abortion, corpus luteum or follicular cyst, ovarian torsion, endometriosis, gastrointestinal disorders, dysfunctional uterine bleeding, mittelschmerz, and intrauterine pregnancy.

PID is commonly confused with ectopic pregnancy. The signs and symptoms may be identical, and the same population is at risk. A significant percentage of normal intrauterine pregnancies are associated with pelvic pain and vaginal bleeding in the first trimester, as are almost all cases of nonviable intrauterine pregnancies. Rupture of a corpus luteum cyst of pregnancy is associated with a positive pregnancy test, pain, and a tender pelvic mass—identical to signs and symptoms of ectopic pregnancy.

Gastrointestinal disorders to be differentiated include appendicitis, diverticulitis, irritable bowel syndrome, and gastroenteritis. Nephrolithiasis should also be considered.

Patients who merit special attention are those with a history of PID, tubal ligation, an IUD, or a recent abortion. An especially high-risk group includes those undergoing infertility treatment with embryo transfer procedures or ovulation-inducing agents.

ED EVALUATION

The evaluation of suspected ectopic pregnancy may be organized into three general categories based on hemodynamic stability (Table 137.2).

TABLE 137.2
Categories for Evaluating Suspected Ectopic Pregnancy Based on Hemodynamic Stability

CATEGORY A

Patients presenting in hypovolemic shock

CATEGORY B

Patients of reproductive age presenting with complaints and physical findings indicative of an acute abdomen but who are hemodynamically stable

CATEGORY C

Patients presenting with abdominopelvic complaints suggestive of an ectopic pregnancy but who are clinically judged to be at low risk of immediate deterioration

The history should emphasize the patient's reproductive past, menstrual history, and risk factors and a chronologic review of the nature and intensity of the symptoms.

The physical examination should focus on changes associated with normal pregnancy and signs of peritoneal inflammation or significant blood loss. Uterine size, adnexal masses, appearance of cervix and os, and rectal examination should be noted. Serial abdominal examinations may aid in the assessment. A pelvic examination should be repeated only as necessary because of the concern that overly aggressive palpation may precipitate rupture.

Laboratory studies should include a urinalysis and a pregnancy test. For patients in categories A and B (Table 137.2), a hematocrit and a blood bank specimen are necessary.

Sensitive qualitative urine pregnancy tests with a human chorionic gonadotropin (β-hCG) threshold of 20 mIU/mL should be used as a screening test for possible ectopic gestation. Modern assays using monoclonally derived, enzyme-tagged antibodies meet this sensitivity requirement, enabling detection of pregnancy 1 week after conception (3 weeks gestational age). Nearly all patients with an ectopic pregnancy will have a positive pregnancy test (16). The chance for a false-negative result exists when the serum β-hCG level is low and the urine is dilute (specific gravity <1.010). Thus, a patient highly suspected of harboring an ectopic gestation who has a dilute urine and a negative urine pregnancy test should have a quantitative serum β-hCG radioimmunoassay.

Patients in category C (Table 137.2) may benefit from serial quantitative serum β-hCG level determinations (17). Serum β-hCG levels rise exponentially during the first 6 weeks of gestation and peak at approximately 100,000 mIU/mL. A single quantitative serum β-hCG value serves to confirm pregnancy, aids in "dating" the pregnancy, and may help in the interpretation of ultrasound results (as described later). Serial quantitative serum β-hCG levels normally double every 2 days in early normal *intrauterine* pregnancies. Abnormal gestations, both intrauterine and extrauterine, have prolonged doubling times (18). Patients in whom serum β-hCG levels do not increase by more than 66% (1.66-fold increase) in 48 hours are likely to have an abnormal pregnancy and should have further evaluation. Serial serum quantitative β-hCG determinations can be used in stable patients to more accurately detect a nonviable intrauterine or ectopic gestation.

The gestational sac of a normal intrauterine pregnancy becomes visible with transabdominal ultrasonography at 5 to 6 weeks of gestation, corresponding to a quantitative β-hCG of 6,000 to 6,500 mIU/mL (8). With transvaginal sonography, a gestational sac is commonly visualized when the β-hCG level exceeds 1,000 to 2,000 mIU/mL (2). The level of β-hCG at which sonographic findings of an intrauterine pregnancy should be visible is often referred to as the *discriminatory zone* (19). Intrauterine pregnancy or findings suggestive of an ectopic gestation may be seen with very low β-hCG levels. Low β-hCG levels should, therefore, not be used as a basis for delaying ultrasonography when ectopic pregnancy is suspected. Ultrasonography results are operator-dependent, and the technique has a high incidence of nonspecific findings with gestational ages earlier than 5 to 6 weeks. With transvaginal ultrasonography, a gestational sac is identified and localized outside the uterus in about 62% of ectopic pregnancies (7). False-negative and false-positive results occur in up to 25% of patients (20). Although a positive diagnosis of ectopic pregnancy can be made by identifying an extrauterine gestation, in practice ultrasonography is more helpful in excluding the diagnosis when it demonstrates an intrauterine

pregnancy, because simultaneous intrauterine and ectopic gestation is uncommon.

The correlation of ultrasonographic findings with quantitative serum β-hCG levels is essential to the efficient diagnosis of ectopic pregnancy. This is especially true when the quantitative β-hCG level is above the discriminatory zone (18). The absence of an intrauterine gestational sac with a serum β-hCG titer above the discriminatory zone suggests ectopic pregnancy with a positive predictive value reported as high as 86% (21). However, β-hCG values as high as 6,567 mIU/mL with no intrauterine pregnancy seen on transvaginal ultrasonography (empty uterus) and eventual diagnosis of intrauterine pregnancy have been documented (22). The ultrasonographic absence of an intrauterine sac, with β-hCG levels below the discriminatory zone, does not allow the definitive diagnosis of an ectopic pregnancy but mandates close follow-up and serial testing.

Serum progesterone levels are sometimes used to screen for ectopic pregnancies. Only 1% to 2% of cases of ectopic pregnancy will be associated with a progesterone level of >5 ng/mL, and only 0.16% of viable pregnancies will be associated with levels <5 ng/mL. Thus, if the progesterone level is abnormally low and the hCG levels are abnormally or erratically rising, a nonviable pregnancy (possibly ectopic) should be suspected. In the ED, progesterone levels are generally not available, but some patients may have had levels determined in an outpatient setting, which may be useful.

Because pregnancy can be detected by laboratory testing at approximately 3 weeks of gestation and by ultrasonography at 5 to 6 weeks, there is a 2 to 3 week period during which a pregnancy can be detected but not located by ultrasound. Routine laparoscopy in this setting would result in a high incidence of unnecessary diagnostic laparoscopies for normal, early intrauterine pregnancies (11). Therefore, patients in category C (Table 137.2) who are stable, reliable, and present during the period of uncertainty are best evaluated by serial serum quantitative β-hCG levels when the initial

sonogram is nondiagnostic. Failure of β-hCG levels to increase normally suggests an ectopic or other abnormal pregnancy.

Culdocentesis is a simple, rapid, and accurate method of detecting intraperitoneal blood. It has been largely replaced by ultrasound in the ED evaluation for ectopic pregnancy (23).

KEY TESTING

- Quantitative serum β-hCG
- Complete blood count
- Type and screen
- Pelvic ultrasound (transvaginal, if available)

ED MANAGEMENT

Management is guided by the patient's hemodynamic status, reliability for follow-up, and the availability of ultrasonography (Fig. 137.2) (7).

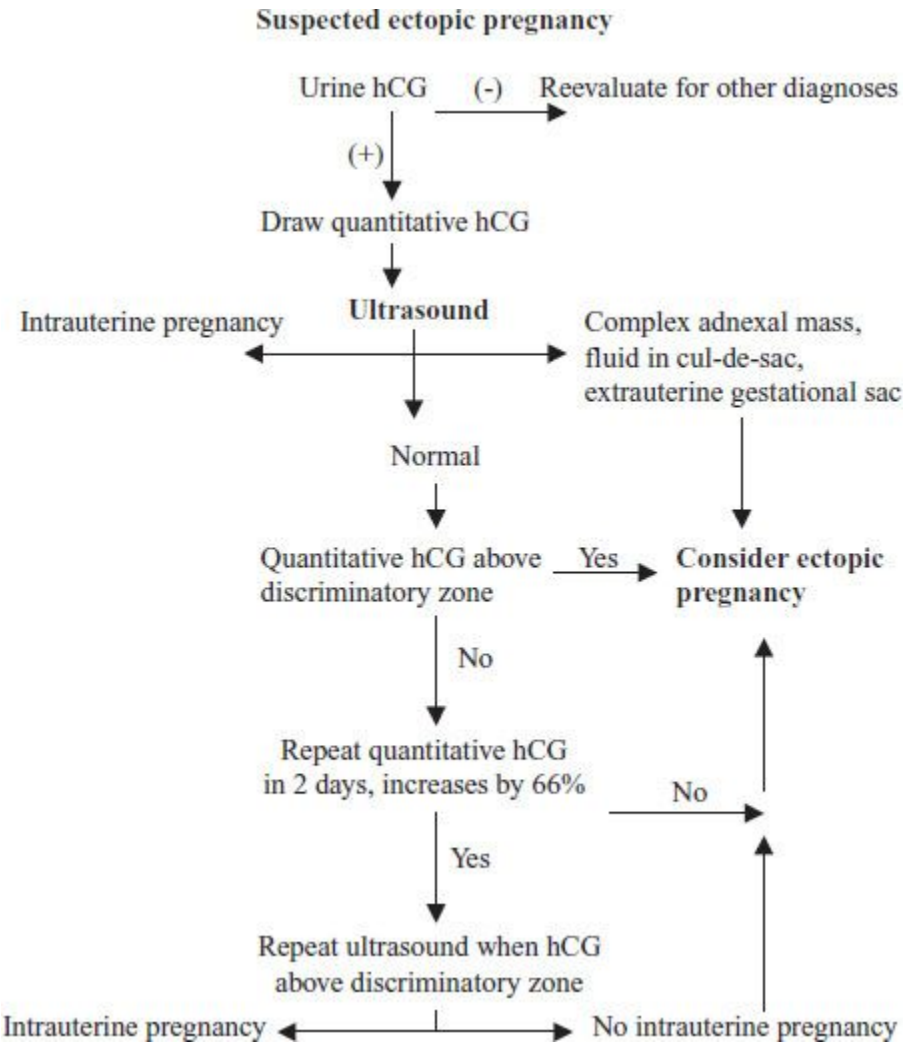

FIGURE 137.2 Algorithm for evaluation and management of suspected ectopic pregnancy.

Patients in category A should be treated for hemorrhagic shock.

- Place the patient in Trendelenburg position
- Administer high-flow oxygen
- Establish large-bore peripheral venous access
- Begin crystalloid infusion
- Obtain baseline blood samples including blood bank
- Transfuse O-negative, type-specific, or cross-matched blood, depending on the response to initial therapy
- Immediate gynecologic consultation

Patients in category B are hemodynamically stable but have potential for rapid progression to category A. Anticipation of fluid

resuscitation and rapid confirmation of the diagnosis dictate the course of evaluation and management. Large-bore venous access should be established. Baseline blood studies include complete blood cell count, Rh typing, and type and screen for potential transfusion. A urine pregnancy test and quantitative β-hCG should be rapidly performed and, if positive, followed by ultrasonography. Patients in category B, by definition, have an acute abdomen and therefore warrant urgent consultation.

Patients in category C, who are stable and ambulatory, are the most common, and pose the greatest diagnostic and management challenges. Figure 137.2 provides a useful algorithm. The evaluation of a possible ectopic pregnancy starts with a urine pregnancy test for *all* women of childbearing age who present with abdominopelvic pain. The only exception is the woman who has had a hysterectomy. The presence of an IUD, tubal ligation, a partner with a vasectomy, or incidental trauma should not deter consideration of an ectopic pregnancy. The diagnosis should be pursued until reasonably eliminated.

Medical Therapy for Unruptured Ectopic Pregnancy

Carefully selected patients with an unruptured ectopic pregnancy may be treated nonsurgically by a gynecologist. Methotrexate may be used for these cases when given orally, intramuscularly, or intravenously, along with leucovorin rescue to prevent toxicity to bone marrow. Recommended regimens include single-dose methotrexate/leucovorin or multi-dose methotrexate/leucovorin. The multi-dose regimen is more effective, but the single-dose regimen is more widely used. Regardless of the regimen that is chosen, more side effects are associated with a higher likelihood of successful treatment. The reported overall success rate for methotrexate (both single and multi-dose therapy) is 89% (24). Methotrexate as a single intramuscular injection can be given to women who are (a) hemodynamically stable (including the absence of a hemoperitoneum), (b) highly compliant, (c) have an initial β-

hCG level <5,000 IU/L, and (d) have no evidence of fetal cardiac activity (6).

Patients treated medically for ectopic pregnancy may experience abdominal pain 3 to 7 days after treatment. This is thought to be secondary to methotrexate-induced tubal abortion. It may be difficult to differentiate expected pain from pain owing to rupture of a persistent ectopic pregnancy. Patients presenting with abdominal pain in this timeframe after methotrexate administration should have a complete blood count and ultrasound to rule out significant free fluid in the cul-de-sac and should be evaluated for other causes of abdominal pain. The patient may need consultation and/or admission to the hospital for observation. Hemodynamic instability or a falling hematocrit mandates surgical intervention.

Stable patients with an ectopic pregnancy and no cardiac activity on ultrasound may be followed up with serial examinations and repeat quantitative β-hCG levels. If the levels continue to fall, no invasive interventions may be necessary. In addition to the repeat β-hCG levels, repeat transvaginal ultrasonic scanning should be considered to ensure reabsorption of the embryo (15).

CRITICAL INTERVENTIONS

- Obtain immediate gynecologic or surgical consultation in patients who are in shock and who have a positive pregnancy test
- Initiate resuscitation with fluids and/or blood as appropriate

DISPOSITION

Given the broad spectrum of presentations and the lack of pathognomonic findings in suspected ectopic pregnancy, there should be a low threshold for requesting consultation from the gynecology, radiology, and surgery services. Early notification of consulting services for patients in categories A and B may allow early mobilization of operating room personnel. The timing for consultation for patients in category C is more flexible and dependent on results of ED testing, local resources, consultant

availability, and whether the patient has a previously established relationship with a gynecologist.

All patients in categories A and B require admission. Category C patients may be discharged with follow-up in 48 hours, except in the following instances:

- No intrauterine pregnancy can be visualized on ultrasonography *in a symptomatic patient* with a quantitative serum β-hCG level above the discriminatory zone.
- There are progressive symptoms or physical findings.
- The patient is unreliable for follow-up.
- There is free fluid on ultrasound.

The usual timing of follow-up is 48 hours, the standard sampling interval for quantitative serum β-hCG levels. Most outpatients will be evaluated by this method. A system should be in place to follow up on serial hCG levels or pathology results in women who have passed tissue or undergone uterine evacuation procedures in the ED for suspected incomplete abortion. If the pathology report shows "no chorionic villi," ectopic pregnancy is the likely diagnosis, and the patient should be urgently referred to an obstetrician/gynecologist or the ED for further evaluation.

In general, patients should be transferred only if the hospital lacks the diagnostic, surgical, or gynecologic resources required to manage the patient.

Common Pitfalls

- Failure to consider the diagnosis of ectopic pregnancy, especially in women with few signs or symptoms.
- Clinical findings consistent with ectopic pregnancy should outweigh any single negative test result.
- Delays have been documented in cases that involve women who have undergone tubal sterilization, women with an IUD in place or recently removed, and women who have undergone a recent spontaneous or therapeutic abortion. Ectopic pregnancy does occur in these groups and must be ruled out.

CHAPTER 138

Hyperemesis Gravidarum

Lori Weichenthal

Although nausea and vomiting are quite common in pregnancy, affecting 70% to 85% of all pregnant women, hyperemesis gravidarum, the most severe manifestation of this disorder, is far rarer, with an incidence rate of only 0.3% to 2% (1,2). Defined as persistent vomiting accompanied by weight loss exceeding 5% of prepregnancy weight that is often associated with ketonuria, severe dehydration, and electrolyte imbalance, hyperemesis can cause significant maternal morbidity if not treated early and aggressively (3). Although the pathogenesis of hyperemesis remains unknown, many theories relate it to hormonal, neurologic, metabolic, toxic, and psychogenic factors. It is agreed that human chorionic gonadotropin (hCG) serum levels are a likely causative factor, given that they peak in the first trimester when severe nausea and vomiting are typically seen and that hyperemesis is more common in women with multiple fetuses and gestational trophoblastic disease, both of which are characterized by higher serum hCG levels (4,5).

CLINICAL PRESENTATION

Hyperemesis gravidarum is a clinical diagnosis, suggested by the findings of intractable vomiting, weight loss, and ketouria beginning in the first trimester of pregnancy. Abdominal pain and fever are uncommon in hyperemesis and should suggest an alternative diagnosis. The onset of symptoms is typically between 4 and 10 weeks of gestation, and hospitalization rates peak at 9 to 10 weeks

(6). Nausea and vomiting that develop beyond 10 weeks of gestation are generally thought to be due to another cause.

Patients with hyperemesis have few distinct physical findings besides those associated with dehydration, such as vital sign abnormalities (tachycardia with or without hypotension), dry oral mucosa, and poor skin turgor. Laboratory abnormalities may or may not be present but can include electrolyte abnormalities such as hypokalemia, metabolic alkalosis, increased blood urea nitrogen; elevated urine-specific gravity and ketonuria; increased hematocrit due to hemoconcentration; mild abnormalities in liver enzyme values; and mild hyperthyroidism.

DIFFERENTIAL DIAGNOSIS

Hyperemesis is generally a diagnosis of exclusion, based on its development in early pregnancy and gradual resolution over time. The differential diagnosis of nausea and vomiting in the pregnant women is extensive and includes disorders related and unrelated to pregnancy (Table 138.1). Some common disorders for the emergency physician to consider include pyelonephritis, appendicitis, cholelithiasis, pancreatitis, gastritis, central nervous system disorders, and toxic and metabolic disturbances. As mentioned, development of nausea and vomiting after 10 weeks gestation should suggest another diagnosis. Other symptoms that should make the EP consider an alternative diagnosis include abdominal pain, fever, headache, diarrhea and/or constipation, abnormal neurologic findings, or hypertension.

TABLE 138.1
Differential Diagnosis of Nausea and Vomiting in Pregnancy

Toxic/Endocrine	Infectious	CNS	Disorders of the Gut
Chemotherapeutics	Gastroenteritis	Migraine	Obstruction
Aspirin	Otitis media	Malignancy	Gastroparesis
NSAIDs	Pyelonephritis	Hemorrhage	GERD
Narcotics		Infarction	Irritable bowel
β-Blockers		Hydrocephalus	Peptic ulcer
Calcium channel blockers		Emotional responses	Cholecystitis
Erythromycin		Psychogenic	Pancreatitis
Sulfonamides		Eating disorders	Hepatitis
Sulfasalazine		Labyrinthitis	Crohn's
Azathioprine			Appendicitis
Anticonvulsants			
Theophyline			
ETOH			
DKA			
Hyper/hypopara-thyroidism			
Adrenal insufficiency			

NSAID, nonsteroidal anti-inflammatory drug; ETOH, ethanol; DKA, diabetic ketoacidosis.

ED EVALUATION

When a pregnant woman presents to the emergency department (ED) with nausea and vomiting, a careful history and physical examination should be obtained to assess the severity of symptoms and physical findings, to determine the need for aggressive resuscitation, and to help exclude alternative causes. Important historical considerations include the time of onset of nausea and vomiting during pregnancy and other related symptoms. It is also important to note any medications or herbal preparations that the patient is using. On physical examination, it is important to assess for signs of dehydration, including vital sign abnormalities, dry oral mucosa, and poor skin turgor. The physician should look for physical examination findings such as fever, abdominal tenderness, costovertebral tenderness, jaundice, goiter, or neurologic deficits that might suggest another diagnosis. A pelvic examination is necessary if the patient has abdominal or pelvic pain, vaginal

discharge, or bleeding. A measurement of weight should also be obtained.

Diagnostic tests to consider include serum electrolytes, a urinalysis, a complete blood count, liver function tests, and serum-free T4 concentrations. An elevated hematocrit and blood urea nitrogen may be present owing to hemoconcentration. Hyper- or hyponatremia and hypokalemia may be present when vomiting has been profuse or persistent. Urinalysis is helpful in gauging the degree of dehydration and ketonuria and for looking for signs of urinary tract infection. Pelvic ultrasound examination might be helpful to exclude gestational trophoblastic disease or multiple gestations. Other imaging studies should be ordered as clinically indicated or as directed by laboratory findings.

KEY TESTING

- Urinalysis and serum electrolytes

ED MANAGEMENT

For patients who appear clinically dehydrated or who have ketonuria, intravenous rehydration should be initiated with D5 lactated Ringer's or D5 normal saline solutions. Typically, an initial bolus of 1 to 2 L is given, and further hydration is determined by the patient's response. Vital signs, symptoms, and urine output should be monitored. Antiemetics are frequently required and should be administered intravenously. Ondansetron has become the most common antiemetic used for the treatment of hyperemesis in the ED, owing to its efficacy and safety profile in pregnancy (class B) (7). Metoclopramide, which is also considered safe in pregnancy, is also frequently used, as are promethazine and prochlorperazine, whose safety in pregnancy have not been well established (Table 138.2). Many recommend giving thiamine, 100 mg IV, to women who have experienced significant nausea and vomiting, as Wernicke encephalopathy is a rare but serious complication of hyperemesis (8).

TABLE 138.2
Antiemetics Used to Treat Hyperemesis

Drug	PO Dose (mg)	PR Dose	IV Dose (mg)	Pregnancy Class
Metoclopramide	10–30	N/A	10	B
Ondansetron	4–8	N/A	4–8	B
Dolasetron	100	N/A	12.5	B
Prochlorperazine	5–10	25 mg	10	C
Promethazine	12.5–25	12.5–25 mg	12.5–25	C

It has recently been suggested that corticosteroids are of potential benefit in the treatment of hyperemesis gravidarum, but they may be associated with an increased risk of oral clefts if used in the first trimester (9). Thus, corticosteroids should be used only as a last resort and in consultation with an obstetrician (1).

CRITICAL INTERVENTIONS

- IV fluid resuscitation as needed
- Antiemetics

DISPOSITION

Women who have intractable vomiting despite aggressive therapy, have persistent electrolyte abnormalities or ketosis, and who have lost more than 10% of their prepregnancy weight generally require admission for further therapy and observation. Approximately 5% of patients with hyperemesis require hospitalization (10)

In patients without laboratory abnormalities, the goal is to correct the dehydration and to ensure that the patient can tolerate oral intake prior to discharge from the ED. Some patients may require an orally or rectally administered antiemetic for use as an outpatient to control their symptoms, though many women can manage their symptoms through behavioral modifications and dietary changes. Women should be counseled to avoid environmental triggers and to eat small, frequent high-carbohydrate, low-fat meals (11). One randomized controlled study found that ginger extract, 1 g daily,

reduced the nausea and vomiting associated with early pregnancy (12). Other adjunctive treatments, including hypnosis, psychotherapy, vitamin B_6 (pyridoxine), and acupressure have also shown promise.

Women who are discharged home should be educated on the expected course of their symptoms, should have close follow-up arranged with their healthcare provider, and should be advised to seek medical help sooner if symptoms change or become more severe or if they develop dizziness or inability to take anything by mouth.

Common Pitfalls

- Failure to aggressively rehydrate women with significant dehydration.
- Failure to consider alternative diagnoses in pregnant women with nausea and vomiting.

CHAPTER 139

Postabortion Complications

Lynne McCullough

Since *Roe v. Wade* in 1973, legalized abortions have become one of the most frequently performed surgical procedures in the United States and one of the most prevalent means of fertility control worldwide (12). The number of abortions performed in the United States had declined each year from 1990 to 2005, followed by a plateau from 2005 to 2008. In 2009, CDC surveillance data reported 784,000 abortions to the Centers for Disease Control, representing the single largest decrease in the last decade (20). Since the US FDA approved mifepristone use for medical abortion in 2000, medical abortions have been growing in popularity as a nonsurgical alternative for termination of pregnancy, with their percentage increasing from 1% in 2000 to 13% of all abortions in 2005 (20).).

In the 3 years following *Roe v. Wade,* the mortality rate associated with surgical abortion decreased from 4.1 to 1.1 per 100,000, and from 1988 to 1997, mortality declined further to 0.7 per 100,000 (2). Although the rate of complications increases with advanced gestational age, serious complications of elective abortion are rare at any age. The overall complication rate is less than 1% (6), and the proportion of women with a reportable complication of medical abortion using mifepristone has been reported to be 2.2 per 1,000 (15,21).

CLINICAL PRESENTATION

Complications after an induced abortion may be divided into (a) early (immediate, or within 3 hours of the procedure), (b) delayed (after 3 hours to 28 days), and (c) late (more than 28 days after the procedure). After elective termination of pregnancy, patients may present to the emergency department (ED) complaining of pain, bleeding, or fever. The degree of discomfort, height of the fever, amount and quality of the bleeding, as well as the patient's past medical history are all relevant pieces of information.

The most commonly encountered complications of induced abortion are delayed, presenting within the first few days after the procedure. Pelvic infections are the most common complication of surgical abortion procedures, occurring in 0.1% to 12% of all patients undergoing elective pregnancy termination (20,23). If symptoms occur within 2 to 3 days of the procedure, approximately 70% have retained products of conception (POC) and secondary infection (6). As infection is common, it is prudent to maintain a high index of suspicion and expedite the administration of antibiotics to minimize complications such as sepsis, chronic pelvic pain, dyspareunia, and infertility. Risk factors for infection include age younger than 20, previous pelvic inflammatory disease, presence of a pathogen in the cervix at the time of the surgical abortion and nulliparous status (22). However, it is important to note that most infections occur in women with no risk factors for disease (20).

Mild bleeding is to be expected after an induced surgical or medical abortion, but persistent or heavy bleeding is unusual and most commonly a result of retained POC (6). After medical termination, patients are generally instructed to seek medical attention if they saturate two full-thickness sanitary pads per hour for 2 consecutive hours (19).

Less commonly, patients present immediately after an abortion procedure with a complication such as uterine perforation, hemorrhage secondary to uterine atony (more common in multiparous patients), retained POC, previously undiagnosed coagulopathy, cervical lacerations, anesthesia complications,

amniotic fluid or pulmonary embolism, or disseminated intravascular coagulopathy (DIC) (5).

Late complications such as cervical stenosis and "*Asherman syndrome,*" the development of intrauterine adhesions, may present to the ED with amenorrhea associated with increasing abdominal distention and cyclical pelvic pain (20). These late complications are relatively uncommon and do not represent true emergencies to be managed in the ED.

DIFFERENTIAL DIAGNOSIS

As the most common chief complaints include abdominal pain, pelvic pain, vaginal bleeding, and fever, the differential is broad. Symptoms may be either a direct result of, or completely unrelated to, the recent pregnancy termination. Postprocedural complications of surgical termination include disorders such as uterine perforation, uterine atony, retained POC, trauma, undiagnosed ectopic pregnancy, endometritis, peritonitis, delayed hemorrhage, and cervical stenosis. The complications seen after medical abortion also include infection and hemorrhage, although uterine bleeding and painful uterine contractions are anticipated consequences (24). Surgical and medical abortion have similar overall efficacy, and failed termination can occur with both approaches (16).

Uterine perforation occurs in 0.01% to 0.1% of first-trimester procedures, and in 3% to 8% of those performed in the second trimester. It is probably underdiagnosed until the time of the surgical procedure and is a rare cause of serious sequelae (13,14,18). Patients may present with complaints of abdominal pain, referred scapular pain, symptoms consistent with bowel obstruction secondary to entrapped mesentery in the perforation, low-grade temperature, rectal pressure, and excessive or persistent vaginal bleeding.

Cervical laceration is a relatively common complication (1%) that is rarely serious (15).

DIC is the most likely form of coagulopathy in the previously healthy patient in the postabortion setting. DIC is more common in

second-trimester terminations, cases of prolonged intrauterine demise, and in cases of massive blood loss (6,20).

Incomplete abortion with retained POC is a relatively common complication of suction evacuation (0.03% to 0.5% of first-trimester abortions) that is characterized by a slightly tender or enlarged uterus in the setting of excessive bleeding (14). This condition should also be considered when heavy bleeding is unresponsive to uterotonic agents.

Acute hematometra, or "postabortal syndrome," a collection of retained blood in the uterine cavity, occurs most commonly in late first-trimester or early second-trimester abortions. The overall incidence is fewer than 5 in 1,000 cases (6,14). Patients typically complain of rapid onset of lower pelvic pain not associated with increased bleeding or unstable vital signs. They may complain of intermittent expulsion of maroon clots with pelvic pressure and low-grade temperature.

Endometritis had a reported incidence of 0.46%, with sepsis in 0.028% in one study from 1990 (14). Infections are typically polymicrobial, including gram-positive and gram-negative anaerobes, facultative or obligate anaerobes, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* (25). *Endomyoparametritis* defines spread of the intrauterine infection to the myometrium and or parametrial structures (i.e., the fallopian tubes; the round, uterosacral, and broad ligaments; and the peritoneum covering those structures). Patients will complain of the postabortal triad of symptoms (pain, bleeding, and fever); foul-smelling discharge may be identified, and leukocytosis is common.

Septic pelvic thrombophlebitis "*right ovarian vein syndrome*" occurs in approximately 1 in 10,000 pregnancies, typically from the late first trimester onward and is the result of progression of endomyoparametritis (8). It can also be secondary to damage to the pelvic venous system during surgical abortion, leading to the development of a thrombus that becomes secondarily infected.

Sepsis and toxic shock syndrome (TSS) associated with Clostridium sordellii following medical abortion has resulted in 6 reported deaths from 560,000 early medical terminations since 2000 (7). In these

cases, the patients presented with minimal signs and symptoms until the infection was fulminant and shock became evident (3). Complicating matters, the side effects of misoprostol (e.g., abdominal discomfort, vomiting, and diarrhea) can be similar to the initial symptoms of patients who ultimately developed toxic shock (11).

Similar symptoms of pain, bleeding, and fever may be produced by disorders unrelated to the procedure, such as appendicitis, pyelonephritis, kidney stone, diverticulitis, pelvic inflammatory disease, endometriosis, menses, and ovarian cyst rupture.

ED EVALUATION

A focused medical history should be taken to include the number of prior pregnancies; the estimated gestational age of the fetus at the time of termination; the date, time, and method of the abortion; any prior history of pelvic infection or known coagulopathy; the patient's Rh status; the results of any preprocedure evaluation, as well as any known complications that may have occurred during or immediately after the procedure.

Patients with significant bleeding or signs of shock require more laboratory testing, including a complete blood count (CBC), type and screen or cross, along with coagulation studies. The evaluation of suspected DIC includes checking platelet and fibrinogen levels, coagulation studies, and fibrin degradation products. Febrile patients should have blood cultures obtained as well. An Rh type should be considered if the patient's type is unknown so that the need for RhoGAM can be identified. A quantitative β-hCG level may be helpful in the event that a missed ectopic or failed abortion is in the differential, and the level may be compared to a prior one, if it is available.

The physical examination should include a complete pelvic evaluation, including direct visualization with a vaginal speculum and bimanual palpation. Pelvic examination may reveal the source of mechanically induced bleeding, as from a cervical laceration or retained POC in the cervical os. It also may reveal the source of pain

and fever. The presence of a nonfirm, boggy uterus suggests uterine atony. A tender uterus may be consistent with either retained POC, continued bleeding into the uterus, or the development of endometritis.

Pelvic ultrasound is a very useful adjunct in the evaluation of postabortive patients in the ED and can demonstrate retained POC, uterine abnormalities that may have led to an incomplete evacuation of the uterus (i.e., an accessory uterine horn or septum), hemoperitoneum, or an unexpected ectopic gestation. A quantitative β-hCG level may also be helpful in diagnosing ectopic pregnancy by demonstrating a persistent level despite anticipated termination of the pregnancy. The β-hCG levels should fall 66% within 48 hours of the abortion procedure but may decline much more slowly over the next several weeks (20).

Clinicians should maintain a high index of suspicion for TSS associated with *C. sordellii* in patients who present with mild flu-like illness after medical abortion. Strong consideration should be given to sending a CBC in these patients, as the index cases have consistently manifested marked leukocytosis and hemoconcentration (owing to third spacing) out of proportion to their mild clinical presentation. In clear cases of TSS, antibiotics such as clindamycin and imipenem–cilastatin should be initiated, in addition to airway and cardiovascular support as needed. Steroid administration and dilation and curettage should be considered in consultation with gynecology; hysterectomy is sometimes necessary (7).

KEY TESTING

- Postabortion bleeding: CBC, type and screen, coagulation studies, quantitative β-hCG, ultrasound
- Fever: Consider blood cultures, lactate, DIC panel, depending on the severity of illness

ED MANAGEMENT

For patients with significant bleeding or signs of shock, two IV lines should be established with normal saline boluses initiated while the

evaluation is taking place. The cause of excessive bleeding can usually be identified by visualization of the cervix on vaginal speculum examination or with bimanual palpation. While evaluating a patient for the potential cause of excessive bleeding, consider uterine tamponade with a Foley catheter balloon, the use of uterotonic agents, and the possibility of pelvic vessel embolization for persistent excessive bleeding (4).

Uterine atony, characterized by a soft, nontender uterus and a steady trickle of blood from the cervix, should be treated with manual uterine massage, intramuscular, intravenous, or intracervical uterotonic agents (Table 139.1) (6,20,25).

TABLE 139.1
Uterotonic Agents (to be Used Sequentially)

Methylergonovine maleate (Methergine)	0.2 mg IM, may repeat and continue oral treatment with 0.2 mg TID for 3 d
Oxytocin[a]	10 U IV bolus or 10 U IM, consider 40 U in 1,000 mL normal saline to infuse at a rate necessary to control bleeding for persistent and severe hemorrhage[b]
Vasopressin	2.5–4.0 units injected directly into the cervix
Misoprostol	400 µg orally
Carboprost tromethamine 15(S)-methyl PGF2α	200 µg/10 mL saline in a transvaginal intrauterine injection or 250 µg IM

[a]Can be given IM or IV. The number of oxytocin receptors in the uterus rises throughout pregnancy; therefore, a diminished response may be seen in first trimester of pregnancy.
[b]Water intoxication can be seen secondary to the mild antidiuretic properties of oxytocin.
Adapted from Stubblefield P, Borgatta L. Complications of induced abortion. In: Pearlman M, Tintinalli J, Dyne P, eds. *Obstetric & Gynecologic Emergencies*. New York, NY: McGraw-Hill; 2003:65–86.

Uterine perforation should be treated empirically with antibiotics when this diagnosis is being considered (Table 139.2), and prompt gynecologic consultation should be obtained. Diagnosis and definitive management are accomplished with explorative laparoscopy or laparotomy when indicated.

TABLE 139.2
Antibiotic Regimens for Postabortal Infectious Complications

Uterine perforation (suspected or proven)	Doxycycline 100 mg PO (if nonsurgical management) and cefoxitin 1 g IV before laparotomy[a]
Endometrial infection, mild, oral regimen	Doxycycline 100 mg BID for 10 d with metronidazole 500 mg TID for 7 d; amoxicillin and clavulanic acid 500 mg TID for 7 d[b]
Ascending infection, abscess or sepsis, IV regimen indicated	Cefoxitin 2 g QID or cefotetan 2–3 g with doxycycline 100 mg BID or clindamycin 600 mg QID[c] or clindamycin 600 mg/gentamicin 3–5 mg/kg/d[d]
Suspected *C. sordellii* infection	Clindamycin and imipenem–cilastatin, consider steroids[e]

Cervical lacerations are usually minor injuries, with bleeding that can be controlled by the topical application of silver nitrate. If more significant lacerations are identified, they can be repaired in the ED with 0-chromic catgut on a CT-1 needle in most cases (6).

The treatment of DIC includes fluid volume and clotting factor replacement with fresh-frozen plasma (FFP), cryoprecipitate, and in severe cases, packed red blood cells. Most important is the attempt to identify and treat any stimulus of DIC, such as retained POCs or infection. Frequent monitoring of coagulation parameters is also indicated. Each unit of FFP (200 to 250 mL) raises fibrinogen levels 25 mg/dL. In early DIC, 4 to 8 units of FFP is usually adequate to restore clotting function (20).

Incomplete abortion with retained POC is usually treated with dilation and curettage. However, if POC are identified in the cervical os on speculum examination, they should be removed immediately to reduce the incidence of continued bleeding.

Acute hematometra, or "*postabortal syndrome,*" should be treated with prompt suction and evacuation of the uterus, which leads to

symptom resolution. A low-grade temperature does not typically indicate infection, and it resolves after evacuation (20).

Endometritis should be treated with uterine evacuation if retained POC are suspected, and outpatient antibiotic regimens for pelvic inflammatory disease are appropriate for mild-to-moderate postabortal endometritis (9). If the patient is toxic or fails outpatient therapy, she should be admitted for parenteral treatment (20). *Endomyoparametritis* requires parenteral antibiotics, as serious complications such as bacteremia may occur in 5% to 10% of these infections, abscesses may form, and the patient may develop a sepsis syndrome. In patients presenting with high fever, tachycardia, marked tenderness to palpation, and leukocytosis, a pelvic ultrasound or a CT of the abdomen and pelvis should be performed to evaluate for an abscess (9).

Septic pelvic thrombophlebitis, or "*right ovarian vein syndrome,*" may be diagnosed by computed tomography or magnetic resonance imaging as well as by prompt clinical improvement after empiric heparin for patients with septic abortion who are unresponsive to parenteral antibiotic therapy (8).

CRITICAL INTERVENTIONS

- Stop any sources of continued bleeding that are accessible to direct pressure or tamponade.
- For hypovolemic or septic patients, initiate supportive care with IV fluids, blood, and antibiotics, as needed.
- Obtain immediate gynecologic or surgical consultation for patients with persistent bleeding or suspected uterine perforation.

DISPOSITION

Patients who present with postabortal bleeding can be safely discharged home following an evaluation that has ruled out ectopic pregnancy, retained POC, and demonstrates that the patient is hemodynamically stable. For patients who require uterotonic agents to assist a poorly responsive uterus, cervical repair of a laceration,

or in whom a uterine perforation is suspected, gynecologic consultation should be obtained and close follow-up arranged if the patient is stabilized for disposition to home.

In cases of mild endometritis, the patient may be discharged on oral antibiotics as listed in Table 139.2. Close follow-up should be arranged, and precautions should be provided to return to the ED or her doctor should include nonresolution of symptoms in 48 to 72 hours or worsening pain, increased fever, or other systemic signs of illness.

Gynecologic consultation and hospitalization are indicated for toxic-appearing or septic patients, those with infection that has spread beyond the endometrium, ongoing hemorrhage, or DIC. Gynecologic consultation should also be obtained when POC are identified, when vaginal bleeding is unresponsive to uterotonic agents, when uterine perforation is suspected, or when an ectopic pregnancy is identified.

Common Pitfalls

- Failure to identify retained POC in the postabortal patient.
- Failure to identify a failed abortion (i.e., an intact gestation).
- Failure to identify ectopic pregnancy in patients who have undergone dilation and curettage but in whom POC were not demonstrated on pathologic examination.
- Inadequate examination of the intravaginal structures to rule out cervical laceration as the source of bleeding.

CHAPTER 140

Hypertensive Disorders of Pregnancy

Jan Marie Shoenberger

During the past 20 years, the incidence of hypertensive disorders during pregnancy has increased. The current leading cause of maternal mortality in the United States is disease of the heart and blood vessels, which includes hypertensive disorders during pregnancy (1,2). It is important to differentiate hypertensive disorders that antedate pregnancy (i.e., chronic hypertension) from a potentially more ominous disease specific to pregnancy—preeclampsia. Preeclampsia is a pregnancy-specific disorder that is defined as an elevation of the blood pressure with new onset proteinuria.

The causes of hypertension in pregnancy are multiple. The Working Group on Research on Hypertension during Pregnancy (3) has categorized hypertension during pregnancy into four categories (Table 140.1).

TABLE 140.1
Classification of Hypertensive Disorders in Pregnancy

Category	Definition
Chronic hypertension	HTN (BP ≥140/90) present before pregnancy or diagnosed before 20 wks gestation
	HTN that is diagnosed during the pregnancy and fails to resolve by 12 wks postpartum
Gestational hypertension	HTN that develops during the pregnancy
	No proteinuria
	If the HTN resolves by 12 wks postpartum, the diagnosis is changed to transient HTN
Preeclampsia/ Eclampsia	HTN presenting after 20 wks gestation with proteinuria (>300 mg in a 24-h collection or ≥1+ on urine dip)
	In the absence of proteinuria, the disease should be highly suspected when HTN appears accompanied by the following symptoms: headache, blurred vision, abdominal pain, low platelets, elevated liver enzymes
Preeclampsia superimposed on chronic hypertension	Underlying diagnosis of HTN with development of new-onset proteinuria (as defined above)
	In women with HTN and proteinuria before 20 wks gestation who have any of the following: sudden increase in proteinuria, sudden increase in blood pressure, thrombocytopenia, increased liver enzymes

Data from Report of the National High Blood Pressure Education Program Working Group on high blood pressure in pregnancy. *Am J Obstet Gynecol.* 2000;183:S1–S22.
HTN, hypertension; BP, blood pressure.

1. Chronic hypertension
2. Gestational or transient hypertension
3. Preeclampsia/eclampsia
4. Preeclampsia superimposed on chronic hypertension

Recognizing and treating elevated blood pressure during pregnancy is important for maternal and neonatal health. Recent evidence shows that elevated blood pressure during pregnancy is a marker of high risk for the development of cardiovascular disease, chronic kidney disease, and diabetes mellitus later in life (4).

CLINICAL PRESENTATION

Chronic Hypertension

In pregnant women, chronic hypertension is defined as elevated blood pressure (BP) that is present and documented before pregnancy. In women whose prepregnancy BP is unknown, the

diagnosis is based on the presence of elevated BP measured on two or more occasions before 20 weeks of gestation. It can also be diagnosed when hypertension is diagnosed for the first time during pregnancy and does not resolve postpartum. Differentiation of chronic hypertension from preeclampsia is important, as the latter may necessitate inpatient management, whereas the former may be treated on an outpatient basis, if mild. The presence of chronic hypertension increases the risk of developing superimposed preeclampsia (the most frequent complication associated with hypertension during pregnancy), abruptio placenta, and preterm delivery. Because it is difficult to determine which pregnant women with chronic hypertension will become complicated, all patients with this diagnosis should be considered high risk and followed closely (5).

Gestational or Transient Hypertension

Gestational or transient hypertension is defined as the development of first-time hypertension after 20 weeks gestation without proteinuria. This diagnosis covers patients with the preeclampsia syndrome who have not yet manifested proteinuria as well as women who do not have preeclampsia. The final determination that the patient does not have preeclampsia can be made only postpartum. If preeclampsia has not developed and the BP has returned to normal by 12 weeks postpartum, the diagnosis of transient hypertension can be confirmed. If the BP elevation persists, the patient now has chronic hypertension.

Preeclampsia and Eclampsia

Preeclampsia is a condition of pregnancy that occurs most often after the 20th week of gestation. By definition, it is characterized by new-onset hypertension (systolic BP of $\leq$140 mm Hg or diastolic BP of $\leq$90 mm Hg) combined with proteinuria, defined as more than 300 mg in 24 hours. In the emergency department (ED), 24-hour urine collection data are typically not available. A rough estimate of the required amount of proteinuria is a reading on a urine dipstick of at

least 1+ protein in a urine specimen with no evidence of urinary infection. Because proteinuria may be a delayed manifestation of preeclampsia, clinicians are advised to be suspicious when new-onset elevated BP is accompanied by any of the following: headache or blurry vision, epigastric or right upper quadrant pain or abnormal laboratory tests, specifically thrombocytopenia and abnormal liver enzymes. These latter elements are the hallmarks of the *HELLP syndrome,* a variant of preeclampsia, which is characterized by hemolytic anemia (*H*), elevated liver enzymes (*EL*), and low platelets/thrombocytopenia (*LP*), as well as by the classic hypertension and proteinuria. The clinical presentation of HELLP syndrome is variable; 12% to 18% of affected women are normotensive and 13% do not have proteinuria (6).

Preeclampsia can be classified into mild and severe disease based on the degree of BP elevation and the presence of the signs and symptoms of HELLP syndrome. In either case, obstetric consultation is advised. Eclampsia is defined as the occurrence of seizures in a woman with preeclampsia. The seizures should not be attributable to other causes.

Preeclampsia Superimposed on Chronic Hypertension

Any existing hypertensive disease predisposes the gravid woman to the development of preeclampsia/eclampsia. The outcome for mother and child with preeclampsia superimposed on existing hypertension is worse than with de novo preeclampsia. Differentiating superimposed preeclampsia from worsening chronic hypertension can be challenging. The diagnosis of superimposed preeclampsia is highly likely if the patient has new-onset or worsening proteinuria, a sudden increase in previously well-controlled BP, thrombocytopenia, or elevated liver enzyme tests.

DIFFERENTIAL DIAGNOSIS

The diagnostic challenge in a gravid patient with hypertension revolves primarily around distinguishing between chronic

hypertension, gestational/transient hypertension, and preeclampsia/eclampsia (see Table 140.1).

Seizures in a woman after 20 weeks of gestation without a previous diagnosis of preeclampsia must be accompanied by two of the following within 24 hours of presentation to be considered eclamptic: hypertension, proteinuria, thrombocytopenia, or increased liver enzyme levels. Eclampsia can also occur in the postpartum period and cases of seizure activity occurring as late as 23 days postpartum have been attributed to eclampsia (7).

ED EVALUATION

When considering diagnoses related to hypertension in pregnancy, it must be ensured that the BP is being measured correctly, with an appropriate sized cuff and with the patient in a seated position. If the BP is found to be elevated, determine which of the four categories of pregnancy-related hypertension is most likely. Assessment of the fetus by ultrasound and fetal heart monitoring is also indicated. Aspects of the history that may be important in determining whether or not the patient has preeclampsia include complaints of headache, visual or neurologic disturbances, and persistent epigastric or right upper quadrant pain. Although some patients develop peripheral edema, this is not a diagnostic criterion for preeclampsia (8).

Any pregnant woman found to have an elevated BP should have a urine dip performed. If protein is detected, preeclampsia should be considered to be the diagnosis until proven otherwise. Other tests that should be ordered include a formal urinalysis, a comprehensive metabolic panel to check renal function, a complete blood count (CBC) to check for thrombocytopenia, serum transaminase levels, and serum uric acid (increased levels suggest the diagnosis of preeclampsia). Women with severe preeclampsia should also have the following tests ordered: serum albumin (indicating the extent of endothelial leakage), lactic acid dehydrogenase (indicating the presence of hemolysis), a coagulation profile, and a blood smear if HELLP syndrome is suspected (3). Evaluation of the fetus by ultrasound and fetal heart monitoring is indicated when there is moderate-to-severe hypertension.

KEY TESTING

- Urine dip for protein
- CBC, metabolic panel, LFTs
- Ultrasound, fetal monitoring

ED MANAGEMENT

Mild-to-moderate chronic or gestational hypertension is less likely to produce end-organ damage, and treatment has been shown to neither improve neonatal outcomes nor prevent superimposed preeclampsia. A recent Cochrane review on this topic concluded that there is insufficient evidence to guide how tightly hypertension should be controlled to improve maternal and neonatal outcomes for pregnant women with nonsevere pre-existing or nonproteinuric gestational hypertension (9). However, there is general agreement that BP in the range of 150 to 160 mm Hg systolic and/or 100 to 110 mm Hg diastolic and greater should be treated.

Methyldopa, labetalol, and nifedipine are oral agents commonly used to treat chronic hypertension in pregnancy. Table 140.2 outlines these medications. Oral hypertensive agents to avoid during pregnancy include the ACE inhibitors and angiotensin receptor blockers (ARBs). Treating women at high risk for the disease in early pregnancy with low-dose aspirin (75 mg/d) has been shown to be effective in reducing the incidence of preeclampsia (10).

TABLE 140.2
Oral Medications Used to Treat Mild–Moderate HTN in Pregnancy

Generic Name	Starting Dose	Maximum Dose (24 hrs)	Mechanism of Action	Side Effects
Methyldopa	250 mg bid	4 g	Central acting α-2 adrenergic agonist	Sedation and fatigue, hemolytic anemia, depression
Labetalol	100 mg bid	2,400 mg	α- and β-blockers	Avoid in asthma and CHF
Nifedipine/NifedipineXL (long acting)	10 mg bid/30 mg qd	120 mg	Calcium channel blocker	
Hydralazine	50–300 mg in 2–4 divided doses	300 mg	Direct vasodilator	Headache, nausea, drug-induced lupus (seen with long-term use)

Therapy for preeclampsia and eclampsia is based on basic principles that come from our limited understanding of the disease.

First, delivery of the fetus is the ultimate and ideal treatment for the mother, but the risks to the fetus at the time of diagnosis must be considered. Second, poor perfusion appears to be a hallmark of the disease; thus, measures to improve and maintain organ perfusion (i.e., oxygen, careful BP control) will benefit the patient.

When the diagnosis of preeclampsia/eclampsia is made in the ED, the obstetrician should immediately be consulted. The following actions should be taken:

- Maintain oxygen delivery to both mother and fetus.
- Maintain continuous fetal monitoring.
- Minimize the aspiration risk by placing the mother in the left lateral decubitus position if seizure activity is present.
- In most cases, volume replacement therapy is not indicated except as needed to maintain a urine output of 1 to 2 mL/kg/hr. Overly aggressive fluid therapy may actually precipitate pulmonary edema (11).
- Monitor urine output using a Foley catheter.
- Treat BP (**Tables 140.2** and **140.3**).
- Treat seizures with magnesium sulfate (see below).

As previously noted, the final step in the treatment of preeclampsia/eclampsia involves delivery or termination of the pregnancy with the least harm to the infant and mother. Timing of delivery is determined by the mother's clinical condition and by gestational age, evidence of fetal lung maturity, and fetal compromise (12).

Table 140.3 outlines the most commonly used medications that are used to control BP in preeclampsia/eclampsia as well as severe hypertension without proteinuria.

TABLE 140.3
Medications Used to Treat Moderate–Severe HTN in Pregnancy

Generic Name	Dose	Infusion	Comments
Labetalol	10–20 mg IV then 20–80 mg IV every 20–30 min, maximum of 300 mg	1–2 mg/min	Risk of neonatal hypoglycemia at high doses
Hydralazine	5 mg IV then 5–10 mg every 20–40 min	0.5–10 mg/hr	
Nifedipine	10 mg orally up to 5 doses	N/A	
Sodium nitroprusside	N/A	0.25–10 µg/kg/min	Should only be used in cases refractory to other therapy

Magnesium sulfate is the drug of choice for seizure control in eclampsia, and has been shown to be superior to both diazepam and phenytoin (13). Magnesium therapy should also be employed in severe preeclampsia for seizure prophylaxis. The goal of therapy is to raise the maternal magnesium plasma level to a range of >4 mEq/mL. The most commonly employed protocol in the United States recommends a 6-g IV loading dose over 20 minutes, followed by an infusion at 2 g IV per hour (14). A commonly used loading dose of 4 g will achieve a therapeutic maternal plasma level; the effect, however, is transient, and the level will fall within 60 minutes. The side effects of magnesium sulfate range from mild effects such as flushing, loss of deep tendon reflexes, and double vision, to life-threatening consequences such as excessive bleeding, respiratory depression, muscle paralysis, and cardiac arrest. When magnesium toxicity is suspected (Table 140.4), calcium gluconate 1 g may be administered to antagonize the effects. The antagonism is transient, however, and continuous monitoring is warranted.

TABLE 140.4
Effects of Magnesium Sulfate on the Mother

Serum Level (mg/dL)	Clinical Effects
1.5–2.5	Normal
4–8	Therapeutic for seizure prophylaxis
8–12	Loss of patellar reflexes, double vision, flushing, somnolence, slurred speech
15–17	Muscle paralysis
30–35	Cardiac arrest

Magnesium sulfate administration should continue until 24 hours after delivery. Signs of improvement include a decrease in BP, improvement in sensorium, and an increase in urine output. Magnesium is excreted by the kidney, so in those cases in which urinary output is decreased or in the presence of renal failure, magnesium doses should be adjusted to avoid toxicity. Although there may be an initial decrease in BP for the first 30 to 45 minutes after the initiation of magnesium treatment, the drug itself is not an antihypertensive agent. As such, another drug should be added to the treatment regimen to control BP and minimize further end-organ damage.

Fetal magnesium may have equilibrated with the mother's, causing hypotonia, respiratory depression, or hypotension in the neonate after delivery. Calcium gluconate may be administered to the infant in those cases.

In cases in which eclampsia is complicated by status epilepticus, intubation and muscular paralysis are indicated.

CRITICAL INTERVENTIONS

- Treat the seizures of eclampsia with magnesium sulfate
- Aggressively treat the hypertension of severe preeclampsia
- Emergently consult an obstetrician for patients with suspected preeclampsia or eclampsia, as delivery is ultimately indicated.

DISPOSITION

For patients with chronic or gestational hypertension without proteinuria, outpatient medical management can be considered for individuals with mild–moderate elevations in BP. In cases of

moderate-to-severe hypertension or proteinuria, obstetric consultation should be obtained in the ED. The need for admission of patients with preeclampsia should be determined after discussion with the obstetrician, and discharge should occur only if close follow-up is feasible.

Except in those cases in which a higher level of care is needed, patients experiencing symptomatic preeclampsia or those with eclamptic seizures are not candidates for transfer. The dynamic nature of the disease, the need for continuous monitoring during therapy, and the high fetal and maternal mortality make this disease inappropriate for interfacility transfer.

Common Pitfalls

- The diagnostic elements of preeclampsia—hypertension and proteinuria—may not occur simultaneously, may be present as part of another disease process, or may be present as part of a normal pregnancy.
- During treatment for eclampsia, the serum magnesium level and the patient's clinical condition must be monitored closely to avoid over- or undertreatment.
- Seizure activity in the third trimester of pregnancy or immediately after delivery may be due to eclampsia and requires high-dose magnesium therapy (6-g loading dose). If the patient is not responsive to magnesium sulfate, other etiologies of seizures should be sought.

CHAPTER 141

Third-Trimester Vaginal Bleeding

Moss H. Mendelson

Vaginal bleeding after 20 weeks' gestation is not uncommon and can be frightening to the patient as well as to the physician. Definitive treatment, if required, should be performed by an obstetrician. The emergency physician must stabilize the patient hemodynamically and should be aware of the differential diagnosis, the studies necessary to define the problem, as well as the indications for transfer if limited facilities exist for management of the mother or the premature or distressed newborn.

Placental abruption (abruptio placentae), premature separation of part of the placenta from the uterine wall, complicates 1% to 2% of all pregnancies. Risk factors include hypertension and maternal tobacco and cocaine use. In addition, abdominal trauma with transmission of forces to the uterus can cause shearing of the placenta from its attachments (1).

Placenta previa, which accounts for about 20% of third-trimester bleeding, is a placenta that overlaps the cervix to varying degrees. Placenta previa is more common with a uterus scarred from previous cesarean section and with advanced maternal age. Of placentas that overlie the cervix before 20 weeks' gestation (approximately 5% of pregnancies), <10% remain so at delivery (2). The other 50% of patients who experience late bleeding often have no definite cause identified. It is believed that most episodes of bleeding represent small marginal separations of the placenta, but this cannot usually be proven. Other causes of bleeding in later

pregnancy include vaginal or cervical trauma, lower genital tract infections, polyps, or hemorrhoids.

The alterations in maternal cardiovascular physiology that occur during pregnancy affect evaluation and management, as well as the clinical course of disease. Maternal blood volume expands by about 1.5 L during a normal pregnancy, resulting in a dilutional anemia that is physiologic (hematocrit 32% to 34%). Pregnant patients also manifest a baseline increase in heart rate (90 to 100 beats/min) and stroke volume, resulting in a cardiac output 30% to 40% higher at term than seen in the nonpregnant state. Systematic vascular resistance is decreased, however, and the net hemodynamic result of these changes is a blood pressure lower than that in the nonpregnant state. Finally, the uteroplacental bed does not have any autoregulatory function; placental blood flow is determined strictly by maternal blood pressure and cardiac output. Because of expanded maternal intravascular volume, signs of extensive blood loss can occur late, and significant fetal hypoperfusion can develop before maternal signs of shock are apparent. Pregnancy is also associated with a rise in concentration of many clotting factors (especially fibrinogen), resulting in a hypercoagulable state.

CLINICAL PRESENTATION

The patient with bleeding after 20 weeks' gestation may present with a spectrum of signs and symptoms ranging from painless spotting or bloody mucoid discharge to dark or exsanguinating bleeding and severe uterine pain. Placenta previa most often presents as bright red, painless vaginal spotting. The bleeding is rarely severe (except during labor or after pelvic examination with probing of the cervical os). The patient may already be aware of an abnormal placental location. The patient with placental abruption more often has dark, variable bleeding accompanied by uterine tenderness and irritability, manifested by intermittent or steady cramping. Bleeding between the placenta and uterine wall may result in significant occult blood loss, with maternal and fetal compromise, but without evidence of significant external bleeding.

Fetal distress (heart rate out of the normal range of 120 to 160 beats/min) can occur if a significant degree of separation has occurred. Abruption may also trigger maternal coagulation, thereby resulting in evidence of consumptive coagulopathy, with bleeding from needlesticks, urine, and other sites.

DIFFERENTIAL DIAGNOSIS

The main disorders that must be considered in the pregnant patient with vaginal bleeding are placental abruption and placenta previa. Other possibilities include bleeding from a cervical or vaginal lesion or from a nonvaginal source such as genitourinary (cystitis, urethritis, and nephrolithiasis) or gastrointestinal (hemorrhoids, polyp, and ulcer).

ED EVALUATION

The patient with vaginal bleeding should first be assessed hemodynamically. With significant maternal blood loss, fluid resuscitation should be initiated during the initial evaluation. Blood should be sent for complete blood cell count, prothrombin time, partial thromboplastin time, and fibrinogen levels. The patient's blood should be typed and crossmatched, as blood transfusion may be necessary. The mother's Rh type should be determined and a Kleihauer–Betke test sent to determine whether significant fetomaternal transfusion has occurred (3). Continuous fetal monitoring should be established as quickly as possible in these high-risk patients, so as to identify signs of fetal distress. Bradycardia <120 beats/min, tachycardia >160 beats/min, decelerations, and loss of beat-to-beat variability all can indicate fetal hypoxemia and acidosis, with an increased risk of fetal demise.

History should include known obstetric problems and ultrasonographic diagnoses. Other historical information includes amount of bleeding, passage of clots, character of blood (bright red or dark, older blood), presence of uterine cramping or pain, prior cervical or vaginal lesions or infection, drug use, and history or evidence of abdominal trauma (including domestic violence).

The initial focus of the physical examination should be to determine whether the patient is severely hypovolemic, whether the bleeding is in fact vaginal (as opposed to urinary or rectal), and whether delivery is in progress. Abdominal examination should confirm uterine size as well as the presence of contractions or tenderness to palpation. Though an external inspection is appropriate, *vaginal examination should not be performed in the ED* because it may precipitate severe hemorrhage and fetal compromise.

Ultrasonography is the diagnostic modality of choice for late pregnancy bleeding. The major purpose of ultrasonography is to locate the placenta and define its relationship to the cervix. In addition, information regarding gestational age and general fetal well-being may be obtained. Transabdominal ultrasound (TAS) is usually performed first but is noted to have a false-positive rate of 2% to 6% for placenta previa. False-positives can be caused by obesity, a posterior placenta, a full bladder, or a focal myometrial contraction. Endovaginal sonography (EVS) eliminates many of these false-positives and has been proven safe in many studies. Although TAS is easily performed in the ED and may yield helpful information, EVS should not be done in the ED in patients with third-trimester vaginal bleeding (1,4).

On the other hand, ultrasonography is insensitive for abruption. Findings in abruption are variable and are affected by the type of abruption (retroplacental or subchorionic) and the timing of the study in relationship to the onset of bleeding. Retroplacental bleeding may have a sonographic appearance very similar to that of a normal placenta, creating an area of thickened placenta or an area mistaken for a fibroid or contraction. Marginal bleeding may be recognized sonographically as a hematoma, although the amount of blood identified on ultrasound may significantly underestimate true losses. Evidence of abruption by ultrasound is helpful to the obstetrician in developing a care plan for the patient and can be followed up with serial examinations. A negative study does not eliminate abruption from the differential and, in fact, a patient with late pregnancy bleeding and an ultrasound negative for placenta previa is often assumed to have abruption. With abruption, fetal

monitoring becomes the primary tool for management decisions (1,5).

A vaginal examination is ideally performed after ultrasonography, by the obstetrician, in an operating suite capable of rapid surgical delivery with fetal resuscitation, in the event that severe bleeding is triggered. If immediate obstetric consultation is not available, patients with significant bleeding should be prepared for transport to a facility that is able to provide appropriate obstetric and neonatal services. In this situation, if the bleeding is not severe, a cautious vaginal examination in the ED is reasonable, after placenta previa has been excluded with transabdominal ultrasonography. The purpose of the examination is to exclude vaginal or cervical lesions that cause bleeding. Neither fingers nor instruments should be placed in the cervical os, because uncontrolled bleeding from a placenta previa can be triggered by such manipulation.

KEY TESTING

- Transabdominal ultrasonography to locate the placenta and obtain an overview of fetal age and status
- Fetal Monitoring should be initiated early
- Type and screen, CBC, PT, PTT, and fibrinogen level

ED MANAGEMENT

Prehospital triage of the woman with bleeding after 24 weeks of gestation (as estimated by the uterus being palpable above the umbilicus) should be to a facility that can manage a potentially high risk or premature delivery. The prehospital management should consist of assessment of the amount of bleeding from evidence at the scene and the degree of current perineal bleeding, administration of maternal supplemental oxygen, positioning of the patient on her left side, and intravenous administration of fluids en route.

For patients with late pregnancy vaginal bleeding, the ED should ideally be a place of cardiovascular stabilization and triage only; there is a paucity of evidence in this area, and case-by-case decision making by the obstetrics team is mandatory. If there is

hemodynamic compromise secondary to hemorrhage, fluid resuscitation should be initiated rapidly with crystalloid. In the mother with rapid exsanguination, O-negative blood and the use of massive transfusion protocols may be required. In cases of severe bleeding, especially with abruption, disseminated intravascular coagulation (DIC) should be anticipated. The blood bank should be notified of the potential need for fresh frozen plasma and platelets. Fetal heart rate should be quickly measured, with initiation of continuous monitoring if possible. Rapid transport to the obstetric suite is the goal (1,2,5).

In the patient with less emergent bleeding, referral to the obstetric unit is preferred for definitive diagnosis. The standard method of evaluation is ultrasonography followed by vaginal examination in a delivery suite, where the discovery of a fetus-threatening placenta previa can be treated with rapid delivery. In the patient with presumed or visible abruption, admission to a high-risk prepartum unit for continuous monitoring is appropriate. Continued fetal well-being should always be documented if the patient spends any significant time in the ED, because hypovolemia is frequently detected by signs of fetal distress before there are changes in the mother's vital signs. If the mother is Rh-negative (with an unknown or Rh-positive father) or if a Kleihauer–Betke test is positive for fetomaternal hemorrhage, RhoGAM should be administered. If fetomaternal hemorrhage in excess of 15 mL of fetal RBCs has occurred, additional RhoGAM may be necessary (consider 10 μg for every additional 0.5 mL fetal RBCs) (3).

CRITICAL INTERVENTIONS

- Do not perform an internal vaginal examination in the ED for third-trimester pregnant patients with vaginal bleeding.
- Provide aggressive volume resuscitation as appropriate. Anticipate the need for massive transfusion and DIC in patients with severe bleeding.
- Immediately consult an obstetrician or arrange transfer to a suitable facility if necessary.

DISPOSITION

All patients with late pregnancy vaginal bleeding require obstetric consultation. The only exception is the patient who is discovered to have bleeding from a nonvaginal source, such as an external hemorrhoid. If necessary, interfacility transfer to a high-risk unit should be accomplished after initial diagnosis or assessment by an obstetrician and is usually performed by specialized obstetric or high-risk neonatal transport units. In general, predelivery transport is safest and is associated with the best outcome, but it must be accomplished in a controlled fashion, with personnel capable of supporting the mother and managing fetal distress or a premature delivery en route.

Common Pitfalls

- Vaginal examinations should be limited to visual inspection of the perineum to look for obvious nonuterine bleeding sources. Fingers or instruments should *never* be placed in or near the cervix, as uncontrolled bleeding from a placenta previa can result.
- Coagulopathy should be considered in patients with severe hemorrhage, as clotting factors are consumed when significant bleeding occurs with abruption, and coagulopathy can seriously compromise the mother's ability to limit uterine bleeding.

CHAPTER 142

Emergency Delivery

Michael D. Burg

Although the ED and the prehospital environment are suboptimal locations for deliveries, they can and do occur there. Exact incidence data for these deliveries are not available, but studies suggest that prehospital or ED deliveries are uncommon but not rare (1–5). These deliveries are associated with increased rates of maternal and neonatal complications (1,3).

The ED usually lacks sophisticated fetal monitoring devices, practiced obstetrical personnel, and advanced delivery technologies to optimize outcomes for mothers and babies. In addition, pregnant women who receive little or no prenatal care, abuse drugs or alcohol, and have limited access to healthcare are overly represented in the ED patient population (1,6).

CLINICAL PRESENTATION

Pregnant patients present to the ED with various delivery- and pregnancy-related conditions, including: premature rupture of the membranes (PROM), preterm labor, shoulder dystocia, preeclampsia and eclampsia, fetal distress, nuchal umbilical cord, breech presentations, postpartum hemorrhage, prolapsed umbilical cord, and meconium staining. Depending on practice setting and obstetric consultant availability, emergency physicians may be required to manage these patients. A basic understanding of these conditions and an organized approach to their management is essential for treatment of these stress-provoking, challenging patients. Patients in

the third trimester of pregnancy may also present with labor symptoms, such as pelvic cramping and low-back pain.

DIFFERENTIAL DIAGNOSIS

All near-term pregnant women presenting to the ED with abdominal pain should be considered to be in labor until proven otherwise. The challenge lies in differentiating true labor, false labor, and other disorders mimicking labor.

Consider preterm labor whenever a woman in the second half of pregnancy experiences recurrent abdominal or pelvic symptoms lasting more than 1 hour (7). Worldwide, about 10% of infants are born preterm and preterm births result in increased morbidity and mortality (8).

True labor is defined by regular, rhythmic, progressive uterine contractions producing effacement and dilation of the cervix (9). *False labor* (Braxton Hicks contractions) consists of short irregular uterine contractions without cervical effacement or dilation. Braxton Hicks contractions do not intensify in strength or frequency and tend to resolve with mild sedation and analgesia (9). False labor can stop spontaneously or progress to true labor. Alternatively, musculoskeletal low-back pain and many abdominal conditions, such as appendicitis, may be confused with labor pains.

ED EVALUATION

Assessment of a pregnant patient at >20 weeks gestational age with any complaint possibly referable to the pregnancy must include an evaluation for pregnancy-related problems. Fetal distress, preterm labor, imminent delivery, hemorrhage, severe preeclampsia, eclampsia, prolapsed umbilical cord, among other conditions may necessitate immediate ED management or transfer to L & D.

Perform a focused history and physical examination. Specific relevant history includes the presence and character of uterine contractions, vaginal fluid leakage, vaginal blood loss, and past medical and surgical history with an emphasis on obstetric and gynecologic history.

Scant dark vaginal blood loss generally signals “bloody show” or passage of the cervical mucous plug. Active or large-volume vaginal bleeding may indicate placenta previa (generally painless) or placental abruption (most often painful) (10).

Patients in active labor generally present with abdominal or back pain or cramps although some experience symptoms such as nausea, vomiting, urinary urgency, incontinence, and anxiety. Some – notably teenagers – may deny any possibility of pregnancy or missed menses.

Review the patient’s prenatal care record noting any complications associated with the present pregnancy. Detail the history of present illness. Fever, chills, headache, visual disturbances, seizures, excessive weight gain, fluid retention, and epigastric or right upper quadrant abdominal pain are important review of systems findings.

Maternal vital signs should be within the normal range for the stage of pregnancy and appropriate to the clinical setting. If fever, hypertension, hypotension, tachypnea, or tachycardia occur, they must be investigated.

Assess the fetal heart rate (normal third trimester range, 120 to 160 beats/min) with either hand-held Doppler or transabdominal ultrasound. Ultrasound allows a more complete pregnancy evaluation and reveals fetal presentation and gestational age, fetal cardiac activity and breathing, amniotic fluid volume, placenta previa, or placental abruption among other conditions.

Perform a general physical examination focusing first on the airway and cardiopulmonary system, neurologic function, and the gravid abdomen. Note any edema, particularly of the face and hands. Fluid retention often accompanies normal pregnancy; however, edema or proteinuria with hypertension, headache, or visual changes and right upper quadrant or epigastric discomfort suggests preeclampsia (7).

Abdominal examination, augmented by transabdominal ultrasound, concentrates on approximating the fetal age. In the hypotensive, tachycardic, or febrile gravida, important etiologic clues may be found during the abdominal examination. Place the

hypotensive gravida in left lateral decubitus position to reverse hypotension caused by the gravid uterus compressing the inferior vena cava and compromising cardiac filling. However in appropriate circumstances consider other causes of hypotension including blood loss, sepsis, and dehydration.

By 20 weeks of gestation, the uterine fundus is generally level with the umbilicus. From 20 to 34 weeks, the distance from the pubic symphysis to the fundus in centimeters approximates the gestational age in weeks (7).

Time permitting (and/or ultrasound unavailable) use Leopold Maneuvers to evaluate fetal position (Fig. 142.1). First palpate the uterine fundus to locate the head, or the buttocks and legs. Next, palpate the uterine sides to identify the fetal back. Finally, palpate just above the pubic symphysis to feel which fetal part is low in the pelvis. In most cases the round hard fetal head will be palpable in the lower pelvis. Ultrasound is far more reliable than these maneuvers to determine fetal lie (7).

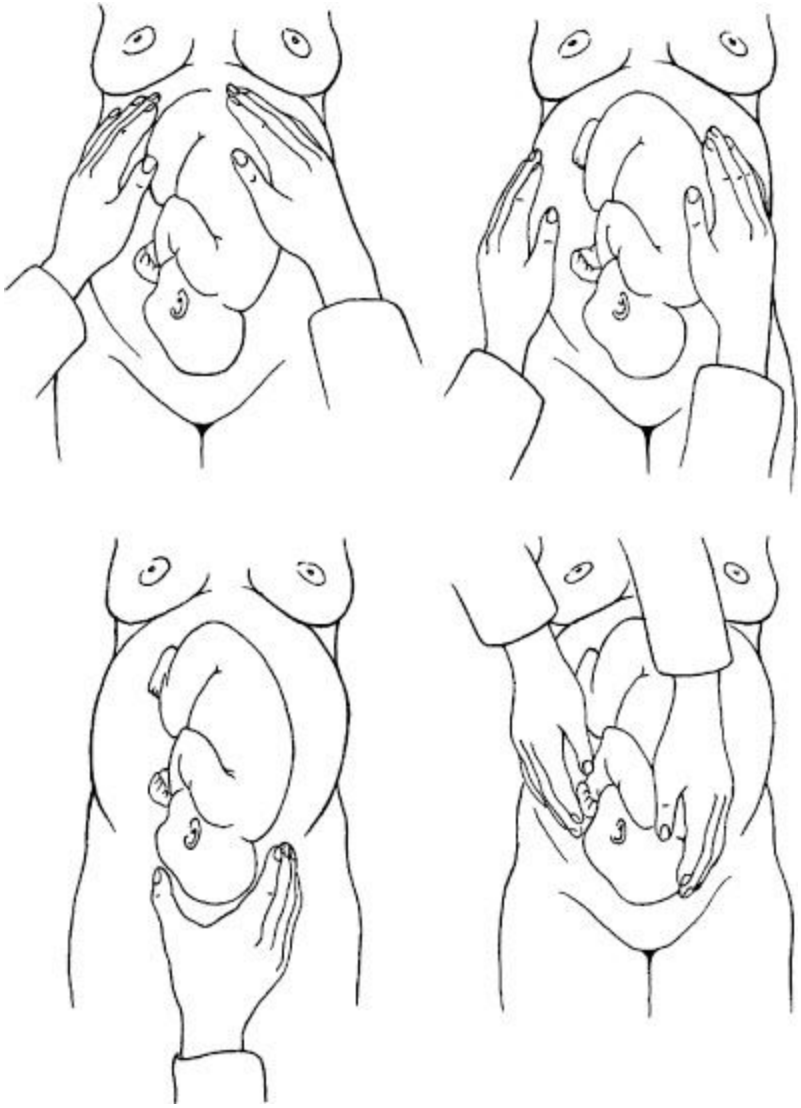

FIGURE 142.1 Leopold maneuvers to evaluate fetal position. (From Beckmann CRB, Ling FW, Laube DW, et al. *Obstetrics and Gynecology*. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2002.)

After the abdominal examination, perform a sterile digital vaginal examination. Vaginal bleeding, which should trigger a concern for placenta previa or placental abruption, is a contraindication to digital vaginal examination. If either of these two entities is suspected, transfer the patient expeditiously to L & D for further evaluation and do not perform a vaginal examination in the ED (see Chapter 141).

Another contraindication to ED digital vaginal examination is suspected rupture of the membranes. Spontaneous rupture of the membranes (SROM), manifested by vaginal leakage of clear or faintly cloudy fluid, is defined as rupture of the chorionic and amniotic membranes and is confirmed by a nitrazine-paper test of pooled vaginal fluid or by microscope slide “ferning” (11,12). SROM may occur before or during active labor and should be strongly suspected on the basis of patient history or when fluid is observed flowing from the cervical os or is seen pooling in the vagina. The nitrazine paper test relies on the fact that amniotic fluid pH approximates that of serum and will turn the normal yellow nitrazine-impregnated paper blue. Vaginal fluid has a more acidic pH. Amniotic fluid forms a characteristic fernlike appearance (ferning) when it is allowed to air-dry on a glass microscope slide (12).

Diagnosing SROM is an important decision branch point for three reasons. First, SROM may signal the onset of active labor (11). Second, umbilical cord prolapse through the cervical os may occur as intrauterine fluid volume suddenly decreases. Third, the risk of intrauterine infection rises with increasing time after SROM (12). To minimize the risk of intrauterine infection (chorioamnionitis or endometritis), a sterile speculum examination should be performed if membrane rupture is suspected and the number of such examinations should be minimized. During the sterile speculum examination, the cervical length, dilation, and consistency are evaluated visually, *not* manually (12).

The primary purpose of the vaginal examination is to evaluate labor progression by assessing cervical effacement (thinning), cervical dilation, and fetal station. Cervical effacement is expressed as a percentage from 0 to 100, with 0% representing a completely uneffaced cervix (about 2 cm in length) and 100% representing a maximally thinned cervix. Cervical dilation refers to the os’s diameter. A 10-cm cervical os is completely dilated. Fetal station is determined by comparing the level of the presenting fetal part to the maternal ischial spines, which represent zero station. Negative station indicates that the presenting fetal part is above the level of

the spines, and positive station indicates that the presenting part is below the level of the spines (7).

PROM refers to membrane rupture before labor onset and occurs in up to 8% of pregnancies. PROM prior to 37 weeks gestational age is preterm PROM (7).

Preterm labor diagnosis is sometimes difficult because of nonspecific symptoms at presentation. Generally, a gravida at <37 weeks gestational age, with regular contractions, cervical dilation of 3 cm or more, and effacement of 80%, is considered to be in preterm labor. Serial examinations are indicated in patients with contractions and only minimal cervical dilation. Ultrasound-aided assessment of fetal breathing may help discriminate between the true and the false labor, as the fetus usually stops breathing in true labor. A high correlation between preterm PROM and preterm labor has been observed. Intrauterine death, nonviability of the fetus, and pregnancy-related maternal medical problems that require early delivery (e.g., severe preeclampsia) are contraindications preterm labor treatment (7).

Laboratory tests, if not already documented, include complete blood cell count, blood type and Rh status, antibody screen, rubella titer, and tests for syphilis, hepatitis and HIV, among others, depending on clinical considerations.

KEY TESTING

- Ultrasound, fetal monitoring
- Ferning and nitrazine

ED MANAGEMENT

Preterm Labor

The preterm labor treatment goal is to prevent or postpone delivery between 22 and 34 weeks gestational age. Unless contraindications exist, begin medical management with admission for lateral decubitus bed rest and maternal hydration. Use tocolytics—uterine contraction suppression agents—to prevent or delay preterm delivery. During the time gained by tocolysis, medications to

stimulate fetal lung maturation are given, and transfer to a facility with specialized neonatal care is arranged (7).

Management controversies exist, but prostaglandin inhibitors (i.e., indomethacin) are reasonable first-line tocolytics. Nifedipine can be used as well. Give 10 mg orally with repeated doses every 15 minutes to a total of 40 mg within the first hour if initial doses are ineffective. Hold for hypotension. If possible, consult an obstetrician before using magnesium sulfate since it may be ineffective and possibly associated with increased infant mortality (13,14).

Tocolysis fails in many patients but treatment may provide time for transfer and the start of fetal lung maturation therapy.

Normal Delivery

Normal delivery involves uterine expulsion of the products of conception—fetus, placenta, and membranes—by the combination of involuntary uterine contractions and voluntary muscular efforts. It is a physiologic—not a pathologic—process; therefore physician involvement in a normal delivery often consists of facilitation and support (5).

Labor is divided into three stages, with phases within to follow its progression and to help identify problems requiring physician intervention (5).

The first stage (cervical stage) begins when contractions become regular and progressively stronger, longer, more frequent, and coordinated (latent phase). Its duration is variable—a few hours to several days—depending on maternal factors. Cervical effacement with minimal dilation generally occurs. With care not to rupture membranes prematurely, identify presenting parts and determine fetal station. Frequent vaginal examinations are unnecessary and increase infection risk (9). The active phase of cervical dilation follows, and is usually shorter, averaging 5 hours in nulliparas and 2 hours in multiparas. The deceleration phase, marked by slowing cervical dilation signals the end of the first stage. Depending on local resources and transfer time, patients in the first stage may be considered for transfer to an obstetrician.

The second stage of labor commences with full cervical dilation and the woman experiencing an urge to push. It culminates with newborn delivery. To facilitate assessment and intervention, position the parturient in either the dorsal lithotomy or left lateral decubitus position. Cleanse and sterilely drape the perineum. Don universal precautions.

During labor's second stage, strong regular 1- to 2-minute uterine contractions occur in 3- to 5-minute cycles. During contractions, encourage efforts to bear down; between contractions, encourage rest. Assess fetal heart rate after each contraction. Between contractions, periodically perform sterile digital vaginal examinations to evaluate labor's progression. Coach the parturient during contractions and communicate calmly between contractions to facilitate a coordinated controlled delivery. Delivery is eminent when the presenting part begins to distend the perineum. During this critical interval, instruct the parturient to pant, not push, allowing slow crowning and controlled delivery of the head.

Episiotomy use in normal delivery has diminished but indications include malpresentations, shoulder dystocia, and eminent perineal tear. A description of this procedure can be found in standard obstetrics texts (7,9).

Use the modified Ritgen maneuver to promote delivery while minimizing maternal perineal injury. Apply direct pressure to the perineum with a draped hand (indirectly putting pressure on the fetal chin), to effect slight fetal head extension. Simultaneously, place your other hand gently on the fetal head, positioning it with its smallest diameter as the presenting part and preventing uncontrolled fetal head movement as it clears the perineum (5,9).

As the head delivers, it will rotate transversely. If a nuchal cord is seen, slip it gently over the fetal head. Doubly clamp and cut an irreducible nuchal cord and perform a rapid delivery. In conjunction with controlled minimal maternal efforts, apply gentle bimanual traction on the fetal head, downward initially then upward, to deliver the anterior and posterior shoulders, respectively. After the shoulders deliver, the body will follow easily. Position the newborn slightly lower than or even with the perineum until the umbilical

cord is clamped and cut. Cut the cord between clamps 4 to 5 cm apart with the proximal clamp applied 5 to 10 cm from the newborn's abdomen (7,9). Dry, bundle, and present the newborn to the mother.

The second stage of labor averages 50 to 60 minutes in nulliparas and 15 to 20 minutes in multiparas (7).

Labor's third stage begins after newborn delivery and ends with placental delivery, usually within 30 minutes. Signs of eminent placental delivery include umbilical cord lengthening, a gush of uterine blood, and the uterus becoming more globular and rising in the abdomen. Maternal efforts are usually sufficient to deliver the placenta but can be aided by *gentle* umbilical cord traction. Keep in mind that uterine inversion is a potentially disastrous complication of pulling on the cord (7). Apply manual pressure just superior to the pubic symphysis to help prevent uterine inversion (5,7). Inspect the placenta and membranes for completeness. Consider manual removal if the placenta is incompletely delivered at 30 minutes (7).

After delivery assess the uterus frequently for an appropriately contracted postdelivery state. Massage the uterus to maintain uterine tone. In addition, titrate oxytocin to decrease the risk of postpartum hemorrhage due to uterine atony.

Perform an initial newborn assessment. Examine the mother for birth canal and perineal tears—which can cause significant blood loss—and repair these promptly (5).

SHOULDER DYSTOCIA

Failure of delivery of the shoulders after delivery of the head (usually due to impaction of a fetal shoulder against the pubic symphysis) is termed shoulder dystocia and complicates up to 2% of vaginal deliveries (12,15,16). The risk of shoulder dystocia rises with fetal weight. Suspect this complication when the anterior shoulder fails to deliver or when the fetal head appears and then retracts into the introitus ("turtle" sign) (12).

Shoulder dystocia contributes to neonatal morbidity and mortality and is associated with aspiration, asphyxia, brachial plexopathies,

and humeral and clavicle fractures (5,15). Maternal postpartum hemorrhage risk is increased as well (15).

Manage this complication by reducing time between delivery of the fetal head and body and minimizing traction on the fetal head and neck, which can worsen the shoulder impaction and/or cause fetal injury (5). A variety of maneuvers to accomplish these goals have been described and it is unclear about which of them—alone or in combination—is best (15–17). While calling for obstetrical back-up consider the following:

- Bladder drainage—creates anterior space.
- Episiotomy—may allow posterior shoulder delivery.
- Hyperflex the maternal thighs onto the abdomen (McRoberts maneuver) (Fig. 142.2)—moves the pubic symphysis anteriorly and cephalad, may allow delivery of the impacted shoulder.

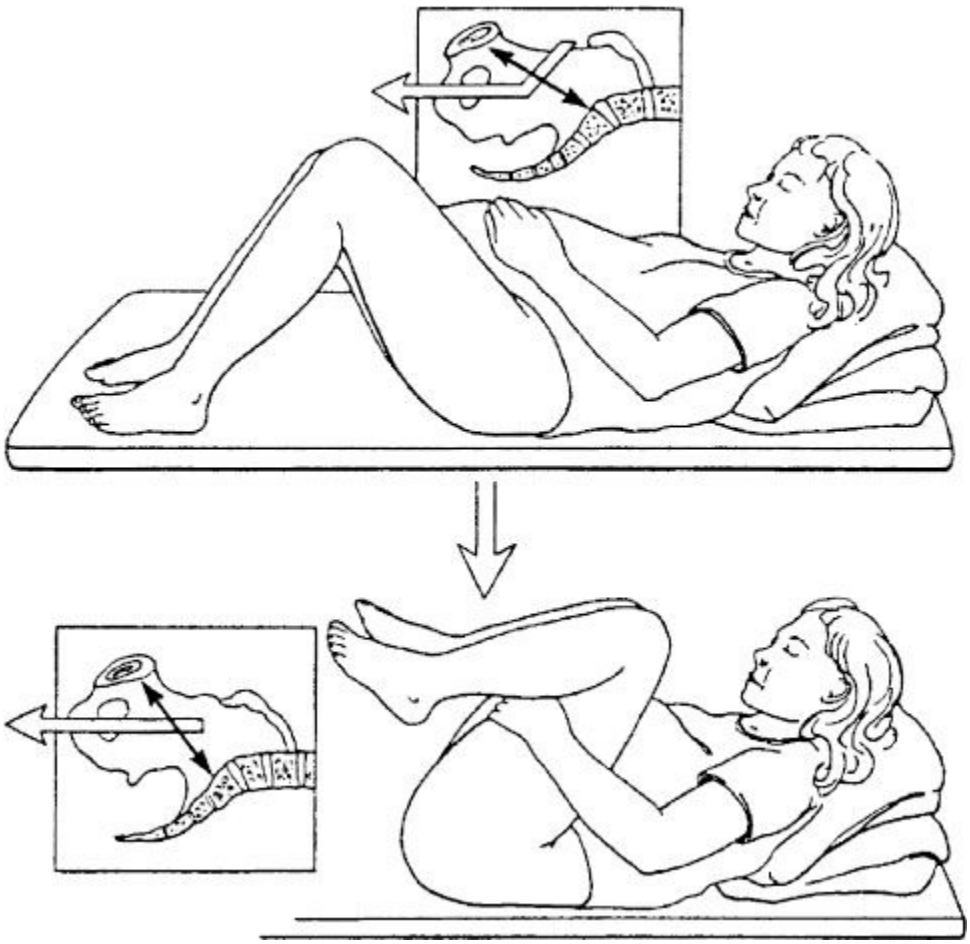

FIGURE 142.2 Hyperflexion of the hips improves pelvic alignment in the management of shoulder dystocia. (From Beckmann CRB, Ling FW, Laube DW, et al. *Obstetrics and Gynecology*. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2002.)

- Having an assistant apply maternal suprapubic pressure while you apply gentle downward traction on the fetal head.

The combination of McRoberts maneuver and suprapubic pressure resolves a substantial number of shoulder dystocias and is safe, quick, simple, and noninvasive. In addition, the "all-fours" maneuver alone (placing the parturient on her hands and knees) resulted in an 83% success rate in one 1998 study (15). More recently, axillary traction has been proposed as a simple effective way to resolve shoulder dystocia after McRoberts maneuver and suprapubic pressure have failed. In this technique, the operator slides his index digit into the posterior axilla, and—with his thumb over the clavicle and his long digit over the proximal humerus—applies axillary traction following the maternal sacral curve, delivering the posterior shoulder first while the anterior shoulder pivots around the pubic symphysis (17). This technique has not been well studied.

Fetal Distress

Measure the fetal heart rate every 15 minutes during labor stage 1 and every 5 minutes during labor stage 2 using Doppler or ultrasound. Begin your assessment at the end of a contraction and continue for a minute. During the third trimester, normal fetal heart rates range from 120 to 160 beats/min (18).

A sustained fetal heart rate >160 beats/min is fetal tachycardia, possibly a manifestation of maternal temperature elevation, medications, fetal distress, and others. Brief (<20 seconds) fetal heart rate accelerations occur often during labor and are normal (9).

Fetal bradycardia is a heart rate <120 beats/min. Brief bradycardic spells—during contractions and ending shortly thereafter—are normal (early decelerations) and likely due to

pressure on the fetal head. Fetal heart rate slowing which lasts long after contractions may signal uteroplacental insufficiency (late decelerations). Decelerations unrelated to uterine contractions may indicate umbilical cord compression (9).

Nuchal Umbilical Cord

After fetal head delivery, check for a nuchal cord visually and manually with a finger sweep of the neck. This occurs commonly, although some reduce spontaneously. Occasionally, two or more nuchal cord loops are found. If possible, simply lift the cord loops up and over the fetal head. If the cord loops will not reduce easily, doubly clamp and cut the cord and rapidly complete the delivery (9).

Breech Presentation

This occurs when the fetal buttocks or legs are closest to the cervix (and consequently deliver first) and complicates a small percentage of deliveries. Breech presentations are closely associated with prematurity and birth weight. Predisposing factors include congenital and uterine abnormalities. Breech presentations heighten perinatal morbidity and mortality risk (7).

Suspect breech presentations during Leopold maneuvers (Fig. 142.1) or during examination of the dilated cervix. Confirm with ultrasound.

Breech delivery is difficult because the presenting parts insufficiently dilate the cervix while successively larger and less compressible parts (especially the fetal head) attempt to pass. Fetal head entrapment and umbilical cord prolapse can occur (5,7).

Breech presentation delivery methods and cesarean section indications can be found in obstetrics texts (7). Immediately consult an obstetrician if a breech presentation is confirmed or suspected.

Prolapsed Umbilical Cord

Umbilical cord passage through the cervix before the presenting fetal part is termed umbilical cord prolapse. It is uncommon but potentially lethal and must be recognized and managed expeditiously (7,19).

Amniotic membrane rupture with a sudden decrease in intrauterine fluid volume is a risk factor for cord prolapse. Suspect cord prolapse and compression if fetal bradycardia occurs (19).

If fetal distress/bradycardia occurs, immediately perform a vaginal examination to check for cord prolapse. Treat by elevating the presenting part off the umbilical cord to restore fetal blood flow (19). Maintain this elevation until delivery occurs (usually by cesarean section) and avoid umbilical cord manipulation (7,19).

Meconium Staining of Amniotic Fluid

Meconium is fetal fecal material and contaminates amniotic fluid in a substantial number of deliveries. Meconium aspiration can cause lung disease and death.

Routine intrapartum suctioning of infants exposed to meconium is no longer recommended. However, endotracheal intubation and tracheal suctioning are indicated for those with respiratory depression (20).

Perimortem Cesarean Section

For pregnant cardiac arrest patients $\leq$24 weeks gestational age consider perimortem cesarean section as a potential lifesaving intervention for the mother and fetus (12,18). Continue resuscitation during and after the procedure because maternal survival after perimortem cesarean section has been reported. Perform the procedure within 5 minutes of maternal arrest to optimize the outcome (18). Obtain immediate obstetric, surgery, and neonatal consultations.

To perform the procedure, create a vertical midline incision into the peritoneal cavity from the maternal epigastrium to the public symphysis. Avoiding bowel and bladder and the underlying fetus, incise the uterus from the fundus to the bladder reflection. Remove

the fetus and doubly clamp and cut the umbilical cord. Consider removing the placenta as well. Within reason, employ sterile/clean surgical technique throughout, provide hemostasis and minimize damage to adjacent maternal organs (10).

CRITICAL INTERVENTIONS

- Attempt to resolve shoulder dystocia with appropriate maneuvers
- Reduce a nuchal umbilical cord
- Elevate the presenting part off of a prolapsed cord
- Obtain early, emergent obstetrics consultation

DISPOSITION

Unless delivery is eminent, transfer preterm labor patients to an obstetric unit capable of providing the required care. If transfer of preterm labor patients is not possible, initiate emergent care as necessary and obtain immediate obstetrical consultation and involvement. Move patients who deliver in the ED to L & D for postdelivery obstetrical care. Patients with delivery complications or episiotomies require postdelivery evaluation and treatment by an obstetrician. Well-appearing term newborns should be transferred to the nursery. Preterm newborns and those in distress require ED resuscitation and transfer to a neonatal intensive care unit.

Common Pitfalls

- Failure to diagnose preterm labor.
- Failure to diagnose and prepare for eminent delivery.
- Failure to obtain early obstetrical consultation.
- Failure to recognize nonspecific signs and symptoms (i.e., low-back pain, abdominal pain) as labor.
- Lack of equipment and expertise for critical neonatal and maternal care.

CHAPTER 143

Postpartum Emergencies

Moss H. Mendelson and Joseph P. Lang

Patients present to the emergency department (ED) with a variety of diseases in the postpartum period. Anatomic and physiologic changes before, during, and after delivery predispose to many of them, and some are life-threatening.

In the third trimester, maternal blood volume is 35% to 50% higher than normal, the plasma volume is increased by 1,200 mL, and the red blood cell volume is increased by 250 mL. Cardiac output is increased by about 1.5 L/min; 600 mL/min of blood flows through the placental site at term. Consequently, uterine and ovarian veins handle a 60-fold increase in volume during pregnancy. In addition, the hypercoagulable state of pregnancy and the trauma from delivery predispose to disseminated thrombosis in the puerperium, experienced as deep venous thrombosis (DVT) or cerebrovascular accident.

The postpartum uterus returns to its nonpregnant anatomic shape and position by loss of cellular fluid and protein and consequent reduction in cell size. Most involution occurs in the first week postpartum. The uterus resumes its intrapelvic position by 2 weeks and normal size by palpation at 6 weeks postpartum. The mean time to ovulation is 70 to 75 days in nonlactating mothers and 190 days in those who lactate. Vaginal bleeding generally diminishes several hours after delivery to a red-brown discharge, which may last through day 3 or 4 postpartum. A mucopurulent discharge may wax and wane over 4 to 6 weeks. Menstruation resumes by about 12 weeks in most nonlactating women (mean, 7 to 9 weeks) but may be delayed in breastfeeding mothers up to 36 months.

POSTPARTUM HEMORRHAGE

Clinical Presentation

Postpartum hemorrhage may be divided into early (<24 hours) and late (between 24 hours and 6 weeks) presentations (Table 143.1). Early postpartum hemorrhage is most often due to uterine atony. Bleeding can be brisk, and shock can develop rapidly. Maternal vital signs are often falsely reassuring, and blood loss can be hidden within the uterus and/or pelvis, making recognition of significant bleeding difficult in some cases. Late causes of hemorrhage include infection, delay in placental site involution, and retained placental parts. There may also be a normal, transient increase in bleeding in the second postpartum week owing to sloughing of the eschar that covers the placental attachment site (1).

TABLE 143.1
Causes of Postpartum Hemorrhage

Early Hemorrhage (<24 hrs)
Uterine atony
Genital tract laceration
Retained placental parts
Placenta accreta
Hematoma
Uterine inversion
Uterine rupture
Coagulopathy
Late Hemorrhage (up to 6 wks)
Infection (endometritis)
Retained placental parts
Delayed placental site involution
Sloughing of placental site eschar

Differential Diagnosis

Uterine atony is responsible for most cases of early postpartum hemorrhage. Failure of the uterus to contract properly allows continued blood loss from the placental site. Myometrial

dysfunction occurs more frequently if the uterus has been overdistended (multiple gestations, hydramnios, multiparity, and macrosomia); if there has been precipitous or prolonged labor, general anesthesia, or previous postpartum hemorrhage; if leiomyomas or amnionitis is present; or if fetal demise or amniotic fluid embolus occurs. Adherent fragments of placenta can also interfere with myometrial contractile function.

Minor *pelvic trauma* occurs in almost all deliveries. However, some vaginal and cervical lacerations may lead to severe hemorrhage. Pelvic vessels can be injured in the process of delivery, causing a pelvic hematoma. Vulvar hematomas are the most common; because the bleeding is bounded by superficial fascial planes, the hematoma usually dissects to the skin and is visible. Deeper vaginal hematomas can be occult and accumulate a significant amount of blood, extending into the pelvic space under the peritoneum. Patients may present with complaints of rectal pressure. Retroperitoneal hematomas are the least common but most dangerous type of hemorrhage. They are associated with significant blood loss, usually the result of trauma to a branch of the hypogastric artery, and can present with shock.

Retained placenta is a common cause of both immediate and late postpartum hemorrhage. Premature, assisted delivery of the placenta increases the risk for retained fragments, which can result in impairment of full uterine contraction and failure to develop hemostasis. *Placenta accreta,* an abnormally deep attachment of the placenta to the myometrium, is suspected if placental delivery is difficult and no cleavage plane between placenta and uterus is found at manual exploration (2,3).

Uterine inversion is uncommon and is more likely if traction is exerted on the umbilical cord. Inversion is usually recognized soon after delivery of the placenta. If the uterine corpus passes through the cervix, the inversion is complete; if not, it is incomplete and may be occult. The patient presents with acute onset of abdominal pain, hemorrhage, and shock. Often, hypotension occurs before significant visible blood loss (4).

Uterine rupture can be catastrophic and often results in fetal and even maternal demise, although the clinical spectrum of morbidity is broad. Factors associated with a rupture include previous curettage, cesarean section (especially with a high uterine incision) or rupture, hydramnios, multiple fetuses, and placenta accreta. Although more common in a previously scarred uterus, rupture of the nonscarred uterus does occur.

Coagulopathy can complicate postpartum hemorrhage of any etiology. In addition, abruption, amniotic fluid embolus, and pregnancy-induced hypertensive disease can cause consumptive coagulopathy, thereby leading to postpartum hemorrhage.

The differential diagnosis of late postpartum hemorrhage includes endometritis, retained placental parts, placental site subinvolution or eschar sloughing, and resumption of menses (1).

ED Evaluation

The care of the patient with postpartum bleeding should begin with an assessment of the extent of blood loss along with concomitant resuscitation if hypovolemia and/or shock are present. In all cases of significant immediate postpartum bleeding, laboratory studies should include a complete blood count (CBC) and coagulation studies. Early establishment of vascular access is critical. A sample should be sent to the blood bank in case transfusion is necessary.

Abdominal and bimanual examinations are necessary to identify the size, position, shape, and tone of the uterus, and the placenta (if available) should be inspected for completeness.

Ultrasonography may aid in narrowing the differential in stable patients with both early and late postpartum hemorrhage. Ultrasound of the uterine cavity can be used to help rule out retained placental tissue by demonstrating a normal uterine stripe. Ultrasound may also be able to distinguish between retained tissue (echogenic mass) and a large intrauterine clot (sonolucent). Occult hematomas can be identified and those patients rapidly triaged to angiography and subsequent embolization. Computed tomography (CT) scanning, although more time-consuming, may also show

hematomas that would be amenable to percutaneous drainage (5). However, the exact role of CT in the patient with postpartum hemorrhage remains unclear.

KEY TESTING

- CBC, coagulation studies, type, and screen
- Ultrasound

ED Management

Patients with significant blood loss require aggressive resuscitation with IV fluids and blood transfusion as needed. If the uterus feels boggy and *uterine atony* is suspected, manual massage should be performed as follows: One hand massages in a circular fashion on the abdomen, with intravaginal fingers massaging the uterus upward. Massage may cause temporary uterine contraction, with recurrent bleeding after relaxation. Pharmacologic treatment (Table 143.2), started concomitantly, includes drugs that increase uterine muscular tone (oxytocin, prostaglandins, and ergot alkaloids). Intravenous infusion of oxytocin is the first-line treatment.

TABLE 143.2
Medical Management of Uterine Atony

Drug	IM Dose	IV Administration	Side effects
Oxytocin	10 U	20–30 U in 1 L normal saline at 200 mL/hr	Hypotension if given as bolus; cramping
Ergonovine maleate	0.2 mg		Cramping
Methylergonovine	0.2 mg		Cramping
15-Methyl-prosta-glandin	0.25 mg		Nausea and vomiting

IM, intramuscular; IV, intravenous.

If bleeding continues, the birth canal should be inspected for trauma. Vaginal or cervical lacerations longer than 2 cm or those that are bleeding should be repaired. Adequate exposure is needed,

which may require general anesthesia and an OR suite. With persistent bleeding or a placenta that appears incomplete, digital exploration of the uterine cavity may be indicated to look for retained placental fragments or uterine rupture. If placental elements remain, an obstetrician should be consulted for further management (2).

Management of *uterine inversion* includes manual restoration of uterine anatomy, followed by removal of the placenta if it remains attached. Manual replacement through the vagina is usually successful. The uterus is compressed between both hands intravaginally and gradually replaced. General anesthesia or tocolytics may be required to allow adequate uterine relaxation. Only after replacement of the uterus oxytocin is started (3).

Refractory bleeding from any source may require emergent surgical intervention or arterial embolization by an interventional radiologist. Uterine rupture, once diagnosed, almost always requires surgery. Retroperitoneal hematomas frequently require invasive intervention. Increasingly, angiographic embolization is being utilized in refractory cases of bleeding. Very high success rates for embolization have been cited, even in cases that have failed traditional surgical intervention. Its use depends upon local resources, availability, and skill levels of the personnel involved (6). Intrauterine tamponade with packing or a balloon device is a temporizing measure that should be considered as surgical or embolization intervention being mobilized. Balloon devices specifically designed for uterine tamponade are simple to use and are gaining acceptance over more traditional methods such as gauze packing (2,7).

Traditional therapy of late postpartum hemorrhage has been curettage. However, placental tissue is often not retrieved, and bleeding may worsen after the procedure. With the ability of uterine ultrasound to rule out retained placental parts, the initial therapy now focuses upon pharmacologic management (Table 143.2). If bleeding stops, the patient should be observed, but curettage may be indicated if bleeding persists or if retained placenta is seen by ultrasound (1).

CRITICAL INTERVENTIONS

- Initiate uterine massage and oxytocin therapy for suspected uterine atony.
- Resuscitate hypovolemic patients with IV fluids and blood products as needed.

Disposition

Many causes of early postpartum hemorrhage are best treated in the labor and delivery suite, where obstetric surgical facilities, including general anesthesia and skilled personnel, are available. The disposition of a patient with late postpartum hemorrhage depends on the amount of bleeding, the response to initial therapy, and the probable cause of the bleeding. Decisions are best made in consultation with the patient's obstetrician.

Common Pitfalls

- Underestimation of blood loss in postpartum hemorrhage. Visual estimations are notoriously inaccurate, and young women may have significant blood loss without developing typical signs of hypovolemia.
- Failure to administer oxytocin, even if uterine atony responds rapidly to manual massage. Oxytocin should be given as well to prevent subsequent uterine relaxation.
- Failure to detect a significant vaginal laceration, the second most common cause of postpartum hemorrhage

PUERPERAL FEVER

Clinical Presentation

Fever in the postpartum period may be classified as early (<48 hours) or late (>48 hours, <6 weeks). Patients may present with symptoms and signs that make the diagnosis obvious, such as findings associated with respiratory or urinary tract infection (UTI). Many causes of puerperal fever, however, have nonspecific

presentations. Lower abdominal pain may be due to persistent contractions or inflammation. Vaginal discharge can be scant or profuse in the face of endometritis or normal involution. Abdominal tenderness and foul-smelling lochia are nonspecific signs, as the tachycardia and decreased bowel sounds. Wound sites should always be examined for tenderness, dehiscence, induration, edema, erythema, and discoloration. Mastitis presents initially with fever, flu-like symptoms, and usually a localized, painful site in the affected breast, with erythema and induration. Septic thrombophlebitis may present with refractory fever or symptoms of pulmonary embolism (PE).

Differential Diagnosis

Early infections most often occur in the uterus and peritoneum after cesarean section or are related to the urinary or respiratory tracts. Late infections include uterine infection after vaginal delivery (usually the result of ascending endogenous organisms), abdominal and episiotomy wound infections, breast infections, or other complications such as abscess or thrombophlebitis. Table 143.3 outlines common causes of puerperal fever.

TABLE 143.3
Causes of Puerperal Fever

Site	Examples	Comment
Pelvic	Endometritis	Single most common cause of puerperal fever; suspect especially after cesarean section
	Wound infection	Requires local exploration, opening, and debridement
	Necrotizing fasciitis	Surgical emergency
	Pelvic abscess	Diagnosed by ultrasound
	Septic thrombophlebitis	Suspect with failure to respond to antibiotics for endometritis
Urinary	Pyelonephritis	Catheterized UA for diagnosis
Pulmonary	Atelectasis	
	Pneumonia	
Breast	Engorgement	Within 24–28 hrs; diffuse, bilateral erythema and distention
	Milk stasis	
	Mastitis	Fever, flu-like symptoms; focal erythema and tenderness
	Breast abscess	
Other	Bacteremia	
	Sepsis	
	Endocarditis	
	IV site	
	Viral syndrome	

UA, urinalysis; IV, intravenous.

Endometritis is infection of the endometrium (the decidua and adjacent myometrium), but often the process extends beyond the uterus into the parametrial tissue, causing a diffuse pelvic cellulitis. The incidence of postpartum uterine infection is 1% to 6% in vaginally delivered women (8). Cesarean section increases both the frequency and the severity of infection: Endometritis occurs in up to 10% to 20% of patients undergoing cesarean section, despite prophylactic antibiotics (9). Other risk factors include premature rupture of membranes, prolonged time from rupture of membranes to delivery, the number of cervical examinations performed, intrauterine manipulation, preterm labor, and low socioeconomic status. Endometritis can lead to sepsis, peritonitis, adnexal infections, pelvic abscess, septic pelvic thrombophlebitis, parametrial phlegmon, and toxic shock syndrome.

Most endometritis is the result of ascending, polymicrobial infection of normal cervicovaginal flora or pre-existing genital tract infection. The placental attachment site and the tissue trauma associated with delivery provide good growth media for bacteria.

Wound infections complicate about 3% of deliveries. Most infections are caused by skin or genital tract flora. Common pathogens include *Staphylococcus aureus,* groups A and B streptococci, *Escherichia coli, Proteus* species, and anaerobes (especially *Clostridium* and *Bacteroides*). If cesarean section is performed emergently or amnionitis is present, a higher rate of wound infection is noted. Many patients initially are given a diagnosis of endometritis but, despite antibiotic therapy, continue to spike temperatures because they require debridement and drainage (9). Complications of wound infection include wound dehiscence, gangrene (especially *Clostridium* species), necrotizing fasciitis (most commonly group A β-hemolytic streptococcal infection), and toxic shock syndrome.

Episiotomy and pelvic floor infections are an uncommon complication of deliveries. The fascial anatomy dictates the depth and spread of the infection and may obscure the findings. Causative bacteria include streptococci and staphylococci, gram-negative enterics, and *Bacteroides* species. Most infections are superficial and mild, limited to the skin and superficial fascia in the area adjacent to the episiotomy. More extensive disease can involve Scarpa fascia, causing a potentially life-threatening necrotizing fasciitis (8).

Septic pelvic thrombophlebitis develops from an infection of the placental site and associated thrombosed myometrial veins. Once established, the process can proceed beyond the local venous system to include the vena cava. Most often the process is unilateral and right-sided. Septic pelvic thrombophlebitis is most common after cesarean section.

Normal breast engorgement consists of distended, firm, nodular breasts in the first 24 to 48 hours postpartum, while lacteal secretion is developing. The condition is painful and often associated with mild transient fever. Milk stasis is the result of incomplete emptying of the milk glands. In 1% to 2% of postpartum

women mastitis develops, which is usually seen 2 to 6 weeks after delivery. *S. aureus* is the most common causative agent.

ED Evaluation

After a detailed obstetric history is taken, the examination should focus on the genital tract, wounds, the breasts, and the urinary and respiratory systems. Examination may reveal tenderness of the lower abdomen and a purulent or foul-smelling lochia. The uterus may be tender and boggy, with parametrial thickening. If an adnexal mass is palpable, it might represent an abscess or an infected hematoma. The entire perineum and genital tract should be inspected for signs of infection from a laceration or episiotomy. A rectovaginal examination should help identify parametritis or other abscesses or hematomas.

Laboratory evaluation should include blood cultures, a CBC, and a urinalysis. Endometrial culture should be considered but may be difficult to interpret because of cervical contamination. Chest x-ray may be indicated if pulmonary symptoms are present, and plain films of the pelvis may reveal soft-tissue gas if necrotizing fasciitis is present.

Further imaging studies may be helpful in puerperal fever when the source is unclear or there is no clinical response to initial antibiotic therapy. CT scanning in endometritis shows intrauterine debris, fluid, and gas in some patients. Ultrasound may reveal endometrial gas, which is sometimes associated with infection but is also seen in clinically well women. Ultrasound, CT scanning, and magnetic resonance imaging can be helpful in the diagnosis of several occult, intrapelvic, infectious sources, such as abscess, infected hematoma, and septic thrombophlebitis. Generally, ultrasound is the initial imaging study, with CT reserved for those with a negative or equivocal ultrasound. Pelvic venography may be required to diagnose septic thrombophlebitis (10).

KEY TESTING

- Ultrasound or CT scan for suspected pelvic abscess

ED Management

Endometritis is treated empirically. If the patient is toxic or has underlying medical problems (e.g., diabetes), or the clinician suspects anaerobic infection, clindamycin and gentamicin or clindamycin and a third-generation cephalosporin should be given. Ampicillin–sulbactam (Unasyn), ticarcillin–clavulanate (Timentin), piperacillin-tazobactam (Zosyn), and imipenem–cilastatin (Primaxin) are all effective single, broad-spectrum antibiotics (11). Data on the outpatient treatment of endometritis are limited. Most patients will require admission, although in some with mild late disease, oral agents can be appropriate. Consultation with an obstetrician is prudent prior to discharge.

Treatment of a wound infection may include opening and debriding the area under adequate anesthesia. If more than local cellulitis is suspected, exploration under general anesthesia should be considered. Necrotizing fasciitis is a surgical emergency requiring immediate consultation. Mortality approaches 100% in patients treated with antibiotics alone and drops to 50% with combined surgical and pharmacologic treatment. Abscesses and some superficial hematomas can be incised and drained (8).

If *septic thrombophlebitis* is suspected, anticoagulation and antibiotics for 7 to 10 days are usually necessary. The incidence of heparin-related bleeding in the postpartum state is low (1% to 2%). Low–molecular-weight heparins (such as enoxaparin) may be used in place of the more traditional use of heparin. Although it is widely prescribed, the utility of anticoagulation has been questioned in several small studies that found no benefit compared to the use of antibiotics alone (10).

Mastitis is usually treated with dicloxacillin or clindamycin orally, along with continued emptying of the breast. With prompt treatment, mastitis usually resolves within 48 hours. Breastfeeding can continue unless an abscess has formed. If an abscess has occurred, drainage is necessary, and breastfeeding should stop. If milk stasis develops without infection, more efficient emptying of the breast is needed. Nursing should continue, and treatment

includes breast support, ice, and analgesia. If the patient is not breastfeeding and conservative methods are not sufficient for relief of pain, suppression of lactation may be helpful. Bromocriptine has been withdrawn for lactation suppression, but other agents are available. Consultation with the obstetrician is indicated.

CRITICAL INTERVENTIONS

- Initiate parenteral broad-spectrum antibiotic therapy for febrile postpartum patients with endometritis.

Disposition

The disposition varies with the type and severity of illness. Patients with mastitis and minor wound infections may be treated as outpatients. Those with more severe infections, including necrotizing fasciitis, septic thrombophlebitis, deep abscesses, and most cases of endometritis, require inpatient parenteral antibiotic therapy.

Common Pitfalls

- Failure to aggressively resuscitate the patient with necrotizing fasciitis, which requires emergent surgical consultation, aggressive debridement, and antibiotic therapy.
- Failure to consider nongynecologic sources of postpartum fever, such as UTI or pneumonia.
- Assuming that breast pain and fever in the first 2 to 4 days postpartum are caused by mastitis. Engorgement often causes these symptoms and does not require antibiotics.

OTHER POSTPARTUM EMERGENCIES

Hypertensive Disease

Pregnancy-related hypertension is classified as *preeclampsia* and *eclampsia,* chronic hypertension, preeclampsia superimposed on chronic hypertension, and transient hypertension. These disorders occur most commonly in the antepartum setting and are discussed

in detail in Chapter 140. However, it should be noted that preeclampsia and eclampsia can both occur postpartum. Treatment is the same as for antepartum patients. New-onset preeclampsia or eclampsia requires admission to the hospital, often in the ICU, and should be managed by an obstetrician.

Neurologic and Endocrine Disease

The onset of some neurologic and endocrine disorders may occur during the weeks after delivery. Postpartum ischemic necrosis of the anterior pituitary (*Sheehan syndrome*) is a complication that may develop if severe postpartum hemorrhage with shock has occurred.

Postpartum *thyroiditis* can develop up to a year after delivery. It is three times more prevalent in type I diabetics. Symptoms of hyperthyroidism generally include fatigue and palpitations, and most commonly occur within 1 to 6 months after delivery. Antithyroid medication is not needed in most cases, as spontaneous resolution occurs in two-thirds. A small number of patients develop persistent hypothyroidism and require thyroid hormone replacement. Hypothyroidism should be considered in the differential of patients with postpartum depression (12).

In postpartum patients with headache, the differential is generally the same as in any other patient, but a few additional causes should be kept in mind. Headache may herald the onset of postpartum preeclampsia. Patients who have had spinal anesthesia during labor can have a “post lumbar puncture headache” that may require a blood patch. Patients with pre-existing migraine headaches often note improvement during pregnancy, possibly due to increased estrogen levels, but the headaches may return during the postpartum period. Treatment is similar to other migraine patients, though ergot alkaloids are contraindicated in the nursing mother (13).

The risk of both hemorrhagic and ischemic stroke peaks in the 6 weeks postpartum, and stroke remains responsible for a significant number of maternal deaths. Predisposing factors such as preeclampsia, chronic hypertension, diabetes, and hypotensive

episodes are noted in about one-third of patients. Although most events are thought to be thrombotic and due to hypercoagulability, embolic sources should also be considered (13). *Cortical venous thrombosis* has also been reported, particularly 1 to 4 weeks postpartum. Initial symptoms are variable and may include headache, lethargy, and vomiting. Seizures are common (up to 30%), and hemiplegia may occur (gradual onset). Care is supportive, although prophylactic anticonvulsant therapy is usually given. Most authors do not recommend anticoagulation, as bleeding frequently follows clot resolution. Mortality may be as high as 20%, despite aggressive supportive treatment (14).

Patients can present with intermittent symptoms due to reversible cerebral vasoconstriction (*postpartum cerebral angiopathy*); the patient presents with headache, vomiting, seizures, and focal neurologic signs. Angiography has shown multiple areas of segmental narrowing in the cerebral arteries, which tend to resolve spontaneously. Finally, postpartum women also have an increased incidence of idiopathic *Bell palsy,* which behaves as in other patients.

Thromboembolic Disease

The risk of thromboembolic disease in pregnancy is roughly five times higher than in the nonpregnant population. Although most thromboses develop in the antepartum period, recent data indicate that two-thirds of PE occur in the postpartum period. PE remains a significant cause of maternal death. Diagnosing DVT and PE can be difficult in the puerperium. Leg edema and calf soreness are common during the postpartum period, and pelvic thrombosis is often clinically silent until PE occurs (15). Treatment of thromboembolic disease in the postpartum generally parallels that of non-pregnant patients.

Cardiomyopathy

Peripartum cardiomyopathy is the development of cardiac failure in the last month of pregnancy or in the first 5 postpartum months, in

the absence of an identifiable cause or prior heart disease. The vast majority of these patients present in the first two postpartum months. In the US, the incidence probably ranges between 1 in 2,500 and 1 in 4,000. Patients often have superimposed preeclampsia, obesity, or coexisting obstetric infection or anemia. Clinically, patients present with signs and symptoms of left heart failure, including dyspnea, orthopnea, and rales. Most patients have nonspecific but abnormal electrocardiograms, often demonstrating ST-T wave changes or left ventricular hypertrophy. Chest radiography reveals cardiomegaly and pulmonary edema. An echocardiogram shows four-chamber enlargement and abnormalities of left ventricular contractility. The workup is directed at excluding other causes of heart failure. The emergency care is the same as other patients with congestive heart failure. Patients can become refractory to medical management, and long-term mortality ranges from 25% to 50%. Ten percent to 20% of patients die during their initial hospitalization. If the heart size returns to normal, the prognosis is good, but cardiomyopathy that persists after 6 months is a poor prognostic sign. PE is a common complication (16).

Psychiatric Disease

A woman's risk of psychiatric disease peaks in the first postpartum year. Fifty percent to 70% of postpartum patients experience "maternity blues." Typically starting on postpartum day 3 or 4, this is a mild depression, most prevalent in the first 2 weeks. It is probably a normal reaction to the stresses of childbirth. Common symptoms include tearfulness, irritability, and emotional lability.

Clinical depression occurs in about 7% to 10% of women, half of whom had no symptoms during or before the pregnancy. Risk factors include personality traits such as anxiety, neuroticism, cognitive style; poor marital adjustment; poor social support systems; and an excess of stressful life events. Stresses during the pregnancy and labor may also contribute (17).

Postpartum psychosis is rare. Usually, the disease has a rapid onset in the first few days postpartum, and mania is a common

feature. The duration of illness is usually 2 to 3 months.

CHAPTER 144

Medical Treatment During Pregnancy

Ryan P. Bodkin and Nicole M. Acquisto

Treating the pregnant patient adds an additional level of complexity to the management of medical emergencies. Pregnant women are often excluded from clinical trials evaluating efficacy and safety and therefore much of the literature regarding medications during pregnancy derives from animal models. Providers must weigh the risks and potential adverse effects of medications on the developing fetus when managing emergent medical conditions. No medication should be prescribed without a clear indication, and medication exposure should be minimized by using the smallest effective dose for the shortest duration possible. This chapter addresses the relative safety of pharmacologic therapy that the emergency provider is likely to consider using in the pregnant patient and the management of common medical problems during pregnancy.

TERATOLOGY

Teratogenesis is the abnormal development of fetal organs. Major malformations occur in 2% to 4% of all newborns, 1% of which may be attributed to the adverse effects of medications (1). The period from 4 to 12 weeks after the first day of the last menstrual period is the time of greatest susceptibility of the embryo to organ malformation (1). During the later stages of pregnancy, drugs may still adversely affect the fetus and newborn, causing complications during delivery or in the postnatal period.

FDA PREGNANCY CATEGORY

In 1979, the United States Food and Drug Administration developed a five-category classification system to guide providers in the interpretation of the teratogenic risk associated with prescription and over-the-counter medications.

- Category A. Adequate, well-controlled human studies have not shown increased risk to the fetus.
- Category B. Animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women.
- Category C. Animal reproduction studies have shown an adverse effect on the fetus; there are no adequate and well-controlled studies in humans, and the benefits from the use of the drug in pregnant women may be acceptable despite its potential risks.
- Category D. Well-controlled human studies have demonstrated fetal risk, but the benefit of use may be acceptable despite its potential risks.
- Category X. Studies have demonstrated animal or human fetal abnormalities and the risk of the drug clearly outweighs the potential benefits.

Practically speaking, category B classification reflects the safest medications in clinical practice. A select list of medications that are discussed in this chapter appears in Table 144.1. A category A classification is rare, as studies on drug safety are generally not performed in pregnant patients. Most often, category D and X medications are contraindicated.

TABLE 144.1
Common Medications Considered Relatively Safe During Pregnancy

Condition	Drug	Condition	Drug
Analgesia	Acetaminophen	Ear, nose, and throat	Diphenhydramine
	Morphine[a]		Chlorpheniramine
	Codeine[a]		Second-generation antihistamines (loratadine, cetirizine)
	Hydrocodone[a]		Dextromethorphan
	Oxycodone[a]		Codeine[a]
	Methadone[a]	Asthma	β-Agonists (albuterol, levalbuterol, terbutaline)
Cardiac	Methyldopa		Ipratroprium bromide
	Clonidine		Corticosteroids (inhaled)
	Hydralazine		Corticosteroids (systemic)[c]
	Labetalol		Epineprhine[c]
	Verapamil		Magnesium sulfate
	Nifedipine extended release	Gastrointestinal	Antacids (aluminum, magnesium, calcium containing)
	Amlodipine		Sucralfate
	Hydrochlorothiazide		H_2-receptor blockers (cimetidine, famotidine, ranitidine)
	Furosemide		Proton pump inhibitors (omeprazole, lansoprazole, esomeprazole, pantoprazole, rabeprazole)
	Adenosine		Ondansetron
	Lidocaine		Prochlorperazine
	Digoxin		Promethazine
Infectious	β-Lactams (penicillin, ampicillin, amoxicillin)		Pyridoxine
	Cephalosporins (ceftriaxone, cefixime)		Metoclopramide
	Nitrofurantoin[b]		Senna
	Aminoglycosides (gentamicin, tobramycin, amikacin)		Docusate
	Macrolides (azithromycin, clarithromycin, erythromycin base, erythromycin ethylsuccinate)	Anticoagulation	Heparin
	Metronidazole (oral)		Low–molecular-weight heparin (enoxaparin, dalteparin)
	Clindamycin (oral)		Fondaparinux
	Azole antifungals (vaginal)		Thrombolytics (alteplase, tenecteplase)[c]
	Acyclovir	Seizure	Carbamazepine
	Valacyclovir		Oxcarbamazepine
	Zidovudine		Benzodiazepines
	Permethrin	Psychiatric	TCAs (amitriptyline, doxepin, imipramine, nortriptyline)
Endocrine	Insulins		SSRIs (fluoxetine, citalopram, paroxetine, sertraline)
			Haloperidol
			Atypical antipsychotics (aripriprazole, olanzapine, paliperidone, quetiapine, risperidone, ziprasidone, clozapine)

[a]Except in long-term use or high doses.
[b]Do not use in the third trimester.
[c]Can use in severe disease.

A select list of medications that are discussed in this chapter appears in Table 144.2. Drugs may have dual classification that reflects safe use during one trimester of pregnancy and unsafe use in another. Information services are available to providers to assist in determining the safety of drugs during pregnancy:

TABLE 144.2
Common Medications that are Contraindicated in Pregnancy

Condition	Drug
Analgesia	Salicylates
	NSAIDs (ibuprofen, naproxen, ketorolac)
	Meperidine
Cardiac	ACE Inhibitors
	Angiotensin-receptor blockers
	Atenolol
	Diltiazem
	Amiodarone
	Ibutalide
Infectious	Nitrofurantoin[a]
	Sulfamethoxazole/trimethoprim[a]
	Fluoroquinolones (ciprofloxacin, levofloxacin, moxifloxacin)
	Erythromycin estolate
	Tetracyclines
	Doxycycline
	Metronidazole (vaginal)
	Clindamycin (vaginal)
	Azole antifungals (oral; fluconazole, ketoconazole, itraconazole)
	Lindane
Endocrine	Oral hypoglycemic agents
Ear, nose, and throat	Brompheniramine
	Decongestants (phenylephrine, pseudoephedrine, phenylpropanolamine)
Gastrointestinal	Antacids (sodium-bicarbonate containing)
	Nizatidine (high dose)
Anticoagulation	Warfarin
	Dabigatran
	Oral factor Xa inhibitors (rivaroxiban, apixaban)
Seizure	Phenytoin
	Phenobarbital
	Primidone
	Valpropic acid
	Valproate sodium
Psychiatric	Lithium

[a]Do not use in third trimester.

PAIN

Acetaminophen (category B) is the analgesic and antipyretic of choice throughout pregnancy. Large population-based studies have demonstrated no increase in congenital malformations with its use (2).

Aspirin (category D) is the most studied analgesic medication in pregnant women. Two large US studies have failed to demonstrate significant fetal risk from aspirin although it readily crosses the placenta. The Collaborative Perinatal Project studied more than 50,000 pregnancies and found no increase in stillbirth, reduced birth weight, teratology, or perinatal death among pregnant women exposed to low-dose aspirin (3). Additionally, the Michigan Medicaid Surveillance Study investigated 1,709 pregnancies with first-trimester exposure to aspirin and found no increase in congenital malformations (4). However, high-dose aspirin in third-trimester pregnancy may be harmful. Near the time of delivery, high-dose aspirin has been shown to increase the risk of infant bleeding, in particular central nervous system (CNS) hemorrhage (4). The use of aspirin near term may also cause premature closure of the fetal ductus arteriosus caused by prostaglandin inhibition (5).

Nonsteroidal anti-inflammatory drugs (NSAIDs) (category C/D), such as ibuprofen, naproxen, and ketorolac, are prostaglandin inhibitors and have been associated with premature closure of the ductus, causing infantile pulmonary hypertension (5). Although the Michigan Medicaid Surveillance Study found no teratogenicity among more than 3,000 first-trimester exposures to ibuprofen, oligohydramnios has been associated with NSAID use (4). It does appear that the adverse effects of NSAIDs on the ductus and amniotic fluid volume are reversible with discontinuation of the drug when used as a tocolytic (4). NSAIDs should be used with caution during pregnancy and they should not be used during the third trimester.

Most opioids are considered safe for use during pregnancy (category B/C). The Collaborative Perinatal Project monitored over

50,000 mother–child pairs. Of these, 563 had first-trimester exposure to codeine and 686 had first-trimester exposure to propoxyphene (3). There was no evidence of a causative relationship to major or minor fetal malformations. The same results were observed in those with exposures to morphine, hydrocodone, oxycodone, methadone, and meperidine. However, since meperidine is extensively metabolized to normeperidine, there is a risk of accumulation. This can cause excitation of the CNS and subsequent seizures and do not make this agent a good choice for pain control in the emergency department (ED) for the pregnant patient.

All of the opioid analgesics are considered category B or C when used in intermittent doses, but all are considered category D if used for prolonged periods or at high doses near term. Chronic opioids can cause respiratory and CNS depression in both mother and newborn. Additional, symptomatic withdrawal in infants can begin 48 hours up to 14 days postpartum. Slow opioid weaning, described as a 10% reduction every 3 days, may be utilized to prevent withdrawal symptoms (5).

ASTHMA

Asthma is a common medication condition to complicate pregnancy. It is estimated that 3.7% to 8.4% of pregnant women in the United States are affected (6). Pregnancy itself has a variable impact on chronic asthma. In patients with chronic severe asthma, pregnancy may cause worsening of the disease due to physiologic changes resulting in a reduction in total lung capacity and functional residual capacity. Poorly controlled asthma is associated with increased fetal mortality and recent guidelines have concluded that it is safer for pregnant women with asthma to be treated with pharmacologic agents than for them to continue with asthma-related symptoms (6).
β-Adrenergic agonists (category C) including albuterol, levalbuterol, and terbutaline have been used safely in pregnancy and do not increase the risk of congenital malformation (1,7). Adverse effects from these medications may cause fetal tachycardia and transient fetal hyperglycemia. The combination of a β-agonist and ipratropium bromide (category B), an anticholinergic agent, is often used during

asthma exacerbations. This combination is safe to use during pregnancy.

Corticosteroids (category B/C) readily cross the placenta where they are rapidly converted to less active forms. Inhaled corticosteroids are the preferred route of administration and considered safe for chronic asthma control (1,7). There is a potential for some systemic absorption and adverse effects from inhaled corticosteroids; however, their use can decrease the need for systemic administration. Systemic corticosteroid administration has been associated with a small fetal risk when used in the first trimester (6). Complications may include preeclampsia, preterm delivery, and low birth weight. In the ED the need for systemic corticosteroids in the pregnant patient may be necessary for acute asthma exacerbation treatment. The use of systemic corticosteroids has been shown to increase the risk of fetal malformations in animal models, but has been used extensively in humans during pregnancy and is not considered teratogenic (6).

Epinephrine (category C) has been shown to reduce uterine blood flow in animal studies and is therefore a concern in humans (5). Epinephrine has also been associated with an increase in fetal malformation. Although selective β_2 agonists are the preferred bronchodilators during pregnancy, epinephrine should be reserved for times when other agents fail to control severe symptoms.

Parenteral magnesium sulfate (category D) has been considered adjunct therapy for severe asthma exacerbations in the ED. It is thought to induce bronchial smooth muscle relaxation and increase bronchodilatory effects of β-agonists. It is likely that a single dose of magnesium is not harmful to the fetus although continuous infusions beyond 5 days for the treatment of preterm labor have been associated with low calcium levels and bone changes in the baby.

DIABETES

Despite advances in the screening and management of diabetes, perinatal mortality among infants of diabetic mothers remains 15% to 25% more than that seen in the general population (8). Pregnancies among diabetic women are more likely to be

complicated by preeclampsia, and the incidence of major malformations is three to four times higher, possibly caused by hyperglycemia during embryogenesis (9). Therefore, maintaining euglycemia during pregnancy is important. Maternal glucose readily crosses into fetal circulation where it can result in fetal hyperinsulinemia. Insulin acts as a potent fetal-growth stimulus, and excessive fetal growth (macrosomia) may result in injury to the fetus or mother during delivery.

During pregnancy, diabetic ketoacidosis (DKA) can develop rapidly and can occur with relatively low serum-glucose levels of 200 to 300 mg/dL. DKA during pregnancy is associated with a high rate of fetal loss and should be treated aggressively with crystalloid fluids and insulin. Insulin (category B/C) is safe in pregnancy. Traditional insulin preparations (insulin aspart, insulin lispro, regular insulin, and insulin NPH) are category B agents and most often used for diabetes control during pregnancy. There is less experience with newer agents (insulin glulisine, insulin determir, and insulin glargine) although most healthcare providers consider these safe to use in pregnancy. More importantly, perinatal morbidity and mortality are related to the degree of glycemic control which may be managed with a combination of insulin products (8).

Gestational diabetes affects approximately 3% of pregnant women. Most patients with gestational diabetes do well with diet modifications, and only 15% will require insulin therapy (8). In this pregnancy-related medical condition, patients cannot increase their insulin secretion to meet the higher demand. There is a low risk of fetal malformations because most of these women are euglycemic during early pregnancy, although fetal macrosomia is still a concern. Oral hypoglycemic agents are contraindicated in pregnancy because they cross the placenta and may cause fetal hypoglycemia as well as excessive fetal insulin secretion (10). Fetal hyperinsulinemia is associated with macrosomia, myocardial hyperplasia, stillbirth, and delayed lung maturation.

HYPERTENSION

Hypertension complicates 5% to 10% of pregnancies, and hypertensive disorders of pregnancy are a leading cause of maternal and perinatal morbidity (11,12). Untreated hypertension increases the risk of fetal death. Care must be taken not to overtreat the condition and cause maternal hypotension with placental hypoperfusion (7).

Centrally acting α-2 adrenergic agonists, such as methyldopa (category B) and clonidine (category C), are commonly used antihypertensive medications during pregnancy and have not been shown to have any adverse fetal or neonatal effects. Methyldopa is the oral medication of choice for the management of chronic hypertension in pregnant women. Hydralazine (category C) is a direct vasodilator and the parenteral medication of choice for the management of severe hypertension in pregnant women. Data are available that demonstrate more frequent, significant hypotension when compared to labetalol or short-acting nifedipine and therefore caution should be taken with its use (11). Angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (category C, first trimester; category D, second and third trimesters) should be avoided in pregnancy because of the risk of fetal renal toxicity and cranial structural defects.

Labetalol (category C) is a commonly used parenteral and oral β-blocker for the management of hypertension. It is not known to be teratogenic and has been shown to increase fetal pulmonary surfactant, which may be advantageous among premature infants. Newborns of mothers taking β-blockers should be monitored closely for neonatal bradycardia, respiratory depression, and hypoglycemia (13). Atenolol (category D) may increase the risk of intrauterine growth retardation (IUGR) when started in the first trimester and should be avoided.

Calcium channel blockers (category C) should be used only as a last resort during pregnancy. Available information mostly addresses the nondihydropyrodines (verapamil and diltiazem). Verapamil can theoretically cause fetal bradycardia, heart block, and hypotension, although clinical experience in pregnant women has not been associated with maternal or fetal adverse effects (13). Nifedipine has

been used more often in pregnancy, but in animal models, the immediate release formulation has been associated with intrauterine growth restriction and fetal death (5). Longer acting formulations such as extended release nifedipine or amlodipine are preferred. Thiazide diuretics such as hydrochlorothiazide (category B) and loop diuretics such as furosemide (category C) are not teratogenic but should be used with caution during pregnancy. An increased risk of perinatal mortality and congenital defects has been associated with these drugs, most likely a result of decreased maternal plasma volume and placental hypoperfusion (7,11,12).

DYSRHYTHMIAS

Sustained arrhythmias may occur more frequently in pregnancy due to hemodynamic, hormonal, and autonomic changes. In unstable, pregnant patients, cardioversion is still recommended (13). All antidysrhythmics cross the placenta (13). Still, several of these agents have long histories of safe use during pregnancy.

Adenosine (category C) is not associated with adverse fetal effects, likely due to its short half-life, and is effective in terminating atrioventricular node–dependent tachydysrhythmias during pregnancy.

Amiodarone (category D) is a class III antiarrhythmic agent that only crosses the placenta to a limited extent. However, it should only be used during pregnancy when absolutely necessary, because of several associated risks (13). The high-iodine content of amiodarone is thought to be responsible for an association with neonatal goiter, hypothyroidism, and IUGR. Ibutilide (category C), a class III antiarrhythmic agent, has been demonstrated to be teratogenic in animal studies and is not recommended during pregnancy (13).

The class IA antiarrhythmic agents, quinidine and procainamide (category C), are considered safe in pregnancy (13). Lidocaine (category C) is a class IB antiarrthythmic agent and is thought to be safe during pregnancy at appropriate doses. Large doses have been associated with low Apgar scores and neonatal lidocaine toxicity. Little information is available regarding the effects of mexiletine,

flecainide, propafenone, and sotalol during pregnancy, although none are known to be teratogenic (13).

Digoxin (category C) is considered safe during pregnancy when given in appropriate doses, although digoxin toxicity has been associated with fetal death and miscarriage (13). It is important to note that serum digoxin levels may decrease by 50% during pregnancy due to increased renal excretion (13). Serum levels must be closely monitored during pregnancy and postpartum digoxin requirements will likely decrease.

THROMBOEMBOLIC DISEASE

Pregnant women are at increased risk of deep venous thrombosis and pulmonary embolism. The incidence of venous thromboembolism is estimated at 0.76 to 1.72 per 1,000 pregnancies (5). This is fourfold greater than the occurrence in the nonpregnant population.

Unfractionated heparin (category C) and low–molecular-weight heparin (LMWH, category B) do not cross the placenta and are the anticoagulants of choice in pregnant patients (10). Due to increased renal excretion and therefore decreased half-life of the medication during pregnancy, twice daily administration is recommended (5). Furthermore, due to the weight-based dose strategy, frequent dose adjustments may be needed throughout the pregnancy. Fondaparinux (category B) is a direct factor Xa inhibitor and may be used as an alternative to heparin products during pregnancy (5). Warfarin (category X) is contraindicated in pregnancy because of its significant association (30%) with congenital malformations (10). The newer oral anticoagulant agents such as dabigatran (direct thrombin inhibitor), rivaroxaban (factor Xa inhibitor), and apixaban (factor Xa inhibitor) are not recommended for use in pregnancy (category C). Adverse effects associated with both dabigatran and rivaroxaban have been observed in animal studies (5).

Thrombolytics (category C) are relatively contraindicated in pregnancy. The theoretical risk of placental abruption and antipartum bleeding should be weighed against the potential benefits of thrombolytic treatment. There are several successful case reports with the use of thrombolytic agents during pregnancy with the

reported maternal bleeding rate of 1% to 6% (5). This is no different from the rate seen in the nonpregnant population.

SEIZURE DISORDERS

The treatment of seizure disorders during pregnancy requires a careful risk–benefit analysis. Although seizures increase the risk of miscarriage and hypoxic injury to the fetus, the risk of birth defects in women taking a single antiepileptic medication is doubled (14). This teratogenic risk is increased with the use of multiple antiepileptic medications (14). The best approach is to use a single agent at the lowest effective dose.

Phenytoin (category D) is a known human teratogen. Fetal exposure to phenytoin is associated with a 7% to 10% risk of IUGR, motor and developmental delays, facial dysmorphia, and limb abnormalities (7). Pregnant women who require treatment with phenytoin are generally also treated with vitamin K and folic acid to decrease the risk of neonatal coagulopathy and neural cord defects, respectively (7,14).

Phenobarbital and primidone (category D) may also contribute to folic acid deficiency and neonatal coagulopathy, though no conclusive evidence of teratogenicity has been demonstrated (7). Respiratory depression and barbiturate withdrawal symptoms may be seen in the neonate exposed to phenobarbital during late gestation.

Carbamazepine and oxcarbapazepine (category C) have been associated with craniofacial defects and developmental delays in infants exposed during gestation (7,14). As with phenytoin and phenobarbital, folic acid deficiency may develop and lead to neural tube defects. If these agents are used, fetal echocardiogram is recommended at 20 to 22 weeks gestation (5).

Valproic acid and valproate sodium (category X) are teratogenic in humans and should be avoided (7,10,14). Neural tube defects occur in approximately 2.5% of infants exposed to valproate in utero, which is up to 10 times that of the general population (7).

Benzodiazepines (category D) easily cross the placenta and concentrate in fetal tissues. A review of the literature found no

increase in the prevalence of congenital malformations in infants exposed to benzodiazepines (5). Nonetheless, with large perinatal doses, newborn apnea, hypotonia, hypothermia, and withdrawal symptoms may be seen.

Little information is available regarding the safety of the newer agents, felbamate, gabapentin, lamotrigine, levetiracetam, and topiramate, during pregnancy. These are all categorized as pregnancy category C agents (5).

PSYCHIATRIC DISORDERS

Tricyclic antidepressants (category C/D) such as amitriptyline, doxepin, imipramine, and nortriptyline and selective serotonin-reuptake inhibitors such as fluoxetine, citalopram, paroxetine, and sertraline have been evaluated in a meta-analysis to determine adverse effects on infant outcomes while administered during pregnancy. Neither of these classes of medications appear to cause major congenital anomalies, but both may be associated with a small increased risk of minor anomalies, prematurity, and neonatal complications (15).

Lithium (category D) is associated with the “floppy-baby” syndrome, characterized by neonatal hypotonia, cyanosis, and poor sucking. Lithium also increases the risk of cardiovascular abnormalities and may affect neonatal thyroid function (15).

Several large prospective trials have failed to demonstrate any teratogenic effects from phenothiazines and haloperidol (category C) (10). It has been recommended that these antipsychotic agents be discontinued 5 to 10 days prior to delivery to decrease the risk of neonatal extrapyramidal symptoms (10). The newer antipsychotic agents, aripiprazole, olanzapine, paliperidone, quetiapine, risperidone, and ziprasidone (category C) and clozapine (category B) have not been associated with teratogenic effects and there is an ongoing Atypical Antipsychotic Pregnancy Registry that is actively collecting information regarding the use of these agents during pregnancy.

GASTROINTESTINAL DISORDERS

During pregnancy, the lower esophageal sphincter is relatively relaxed and pressure on the abdominal contents from the uterus increases the frequency of heartburn symptoms. Similarly, nausea and vomiting are well-known features of early pregnancy and often require treatment.

Antacids containing aluminum, magnesium, and calcium are considered safe during pregnancy and no teratogenicity has been reported from animal studies (16). Sucralfate (category B) is not systemically absorbed and is safe during pregnancy. Sodium bicarbonate–containing antacids should be avoided due to the potential for maternal or fetal metabolic acidosis and fluid volume derangements (5).

H_2-receptor antagonists appear to be well tolerated during pregnancy. Cimetidine, famotidine, ranitidine, and nizatidine are all considered category B agents. Among 460 newborns in the Michigan Medicaid Surveillance Study, cimetidine use was not associated with an increased number of congenital defects (16).

Proton pump inhibitors do cross the placenta. Omeprazole is a category C agent, while others such as lansoprazole, esomeprazole, pantoprazole, and rabeprazole are category B agents. The Swedish Medical Birth Registry evaluated a cohort of 955 infants of mothers exposed to omeprazole, with no difference in birth weight, congenital malformation, or Apgar scores compared to the general population (17). Similarly, a recent cohort study of first-trimester exposure to any proton-pump inhibitor in 840,968 live births found no statistical differences in birth defects (18).

Ondansetron (category B) is considered the first-line treatment of hyperemesis and early pregnancy–induced nausea. Phenothiazine agents such as prochlorperazine and promethazine (category C) are commonly used antiemetics that cross the placenta, but have not been shown to be teratogenic (7,10). The Collaborative Perinatal Project monitored 50,282 mother–child pairs and found no evidence of an increased risk of malformation associated with prochlorperazine or promethazine (19). Metoclopramide (category B) was evaluated in the Michigan Medicaid Surveillance Study, with no significant increase in malformations beyond that expected in the

general population (16). Pyridoxine (vitamin B6) is considered safe to use in pregnancy and a 3- to 5-day course is commonly recommended to decrease vomiting episodes and nausea scores in pregnant women (5).

Laxatives which act locally in the gastrointestinal tract, such as castor oil, senna, milk of magnesia, and docusate, are safe for use in pregnancy.

URINARY TRACT INFECTION

Urinary tract infections (UTIs) are the most common infectious complication during pregnancy. Asymptomatic bacteriuria is present in 1.9% to 9.5% of pregnant women and there is a 20- to 30-fold increased risk of developing pyelonephritis if untreated compared to pregnant women without bacteriuria (20). Bacterial pathogens responsible for UTI in pregnant patients are similar to those in the general population with *Escherichia coli* accounting for more than 75% of cases. Cystitis and asymptomatic bacteriuria should both be treated in the pregnant patient for 3 to 7 days (20).

Pyelonephritis is a serious condition in the pregnant patient. Preterm labor and premature delivery have been associated with pyelonephritis, although the physiologic mechanism for this phenomenon is not clear. Approximately 15% of pregnant women with pyelonephritis become bacteremic. Initial parenteral treatment in the inpatient setting should be considered. Pyelonephritis and other complicated UTIs (e.g., in a diabetic patient) should be treated for 10 to 14 days (20). All antibiotics cross the placenta, but many have been used for a number of years without reports of adverse fetal effects.

Cephalosporins (category B) are the most commonly prescribed antibiotic in this population and are considered safe during pregnancy (10,21).

β-Lactam antibiotics such as ampicillin and amoxicillin (category B) are considered safe in pregnancy (20), although these agents are not often considered first-line therapy for UTI in pregnant patient due to a high percentage of *E. coli* resistance (30% to 50%).

Nitrofurantoin (category B) is commonly used during pregnancy but may cause neonatal hyperbilirubinemia when used in the third trimester and should be avoided during this time.

Sulfonamides are considered safe during early pregnancy. However, during the third trimester, their use is contraindicated because they compete with bilirubin for albumin-binding sites and may cause kernicterus (10,21). Trimethoprim is a folate antagonist and is not recommended during pregnancy, so combination agents such as trimethoprim/sulfamethoxazole (category C) should be avoided (21).

Aminoglycosides (category C) such as gentamicin, tobramycin, and amikacin may be used to treat resistant gram-negative infections in pregnant women (21). Aminoglycosides have been associated with a high prevalence of transient renal dysfunction in the pregnant patient. Fluoroquinolones (category C) such as ciprofloxacin and levofloxacin are contraindicated during pregnancy because of reports of irreversible arthropathy in immature animals.

RESPIRATORY TRACT INFECTIONS

Macrolides such as azithromycin and erythromycin (category B) are commonly used to treat pneumonia in pregnancy (10,21). Clarithromycin is used less often since it is a category C agent. Cephalosporins are category B and safe to use during pregnancy. Respiratory fluoroquinolones (category C) such as levofloxacin and moxifloxacin are contraindicated.

Tetracyclines and doxycycline (category D) should be avoided during pregnancy because of the risk of genitourinary and limb malformations (10,21). Tetracyclines also chelate calcium and may stain teeth and bones if given after 5 months of gestation (10,21).

Streptococcal pharyngitis is not treated differently during pregnancy. Penicillin (category B) and its derivatives are considered safe. In the penicillin-allergic patient, azithromycin, erythromycin, or clindamycin (category B) can be considered.

Antihistamines and decongestants are commonly used for symptomatic relief in patients with upper respiratory infections. However, many over-the-counter medications are not recommended

for use during pregnancy. Diphenhydramine and chlorpheniramine are category B agents and can be used during pregnancy. Brompheniramine (category C) is a well-known teratogen and is contraindicated in the pregnant patient. Second-generation antihistamines such as loratadine and cetirizine are category B agents and considered safe during pregnancy. Decongestant medications such as phenylephrine, pseudoephedrine, and phenylpropanolamine have been associated with teratogenicity in animals and minor fetal malformations in humans and are category C agents. These should be used with caution during pregnancy. Dextromethorphan and codeine (category C) are considered safe for use as antitussive agents during pregnancy.

GENITAL TRACT AND SEXUALLY TRANSMITTED INFECTIONS

Neisseria gonorrhoeae and *Chlamydia trachomatis* cervicitis may cause significant maternal and fetal adverse effects when left untreated (5). Infection with *N. gonorrhoeae* may lead to premature rupture of membranes, preterm labor, and chorioamnionitis (5). In addition, there is concern with neonatal transmission during birth. Cephalosporins (category B) such as ceftriaxone or cefixime are safe for the treatment of *N. gonorrhoeae.* Azithromycin (category B) 2 g administered orally as a single dose may be used for patients who are allergic to cephalosporins (22). To treat *C. trachomatis,* azithromycin 1 gm orally as a single dose can be safely used. Fluoroquinolones and doxycycline are contraindicated during pregnancy (22).

Syphilis can cross the placenta at any stage of pregnancy, with potentially devastating fetal effects. Treatment with parenteral agents such as penicillin G benzathine (category B) is preferred to oral therapy (22). Those with a penicillin allergy should undergo skin desensitization.

Vaginitis caused by *Trichomonas vaginalis* and bacterial vaginosis (BV) may increase the risk of premature rupture of membranes and preterm labor. Oral metronidazole (category B) is the recommended treatment. Multiple studies have failed to show an association between metronidazole during pregnancy and fetal teratogenic or

mutagenic effects (22). Oral clindamycin may also be used, but intravaginal clindamycin cream administered at 16 to 32 weeks gestation is associated with an increase in low birth weight and neonatal malformations (22).

Topical antifungal vaginal creams (including clotrimazole, miconazole, and nystatin) for Candida vaginitis are considered safe during pregnancy (22). However, oral fluconazole, ketoconazole, and itraconazole (category C/D) are associated with fetal malformations and should be avoided during pregnancy.

Human papillomavirus infections during pregnancy may obstruct the vaginal canal and increase the risk of hemorrhage during delivery. Topical pharmaceutical agents such as podophyllin, podofilox, imiquimod, or sinecatechin are not recommended in pregnancy (5). Current treatment recommendations during pregnancy are carbon dioxide ablation, liquid nitrogen cryotherapy, or surgical excitation (5). Herpes virus infection during pregnancy raises concern for perinatal transmission. The neonatal infection rate is nearly 50% with vaginal delivery during a primary maternal outbreak. Acyclovir intravenous and oral as well as valacyclovir (category B) have not been associated with an increase in birth defects compared to the general population in a voluntary data registry of 1,129 pregnant patients (22,23).

In pregnant women with human immunodeficiency virus (HIV) there is a concern for fetal transmission. There are reports of safety and a reduction in perinatal transmission among HIV-positive pregnant women who are treated with zidovudine (24). Pregnant patients with HIV infection can be treated with certain multidrug antiretroviral regimens and this should be coordinated with an infectious diseases provider.

OTHER SELECTED INFECTIONS

Scabies during pregnancy can be treated with pyrethroids. Lindane is potentially neurotoxic and was found to be possibly associated with hypospadias in the Michigan Medicaid Surveillance Study (10).

Varicella has a potentially devastating course in pregnancy. Fetuses exposed to varicella in the first trimester are prone to limb

and digit abnormalities, microphthalmos, and microcephaly. Infection in the last two trimesters is less threatening. Peripartum varicella infection (from 5 days before delivery to 2 days after delivery) places the fetus at high risk for morbidity and mortality. Varicella-immune globulin should be given within 96 hours to an exposed pregnant patient with no history of chicken pox and a negative antibody titer.

IMMUNIZATIONS DURING PREGNANCY

Benefits of vaccinating pregnant women usually outweigh the risks when possible exposure is likely. There is no evidence of increased fetal harm when inactivated viral or bacterial vaccines are given to pregnant women. Live vaccines should be avoided during pregnancy because of the theoretical risk of infection and transmission to the fetus (25). Avoidance of administration during the first trimester is preferred since the vaccination itself may cause high fevers, which have been associated with neural tube defects (25). Commonly immunizations that are safe during pregnancy include hepatitis A, hepatitis B, inactivated influenza, pneumococcal, human diploid cell rabies, tetanus and diphtheria toxoid (Td), and tetanus, diphtheria, and acellular pertussis (TdaP) vaccines. Passive immunization of pregnant women with immune globulin preparations has not been associated with risk to the fetus (25). These immune globulin preparations include tetanus, rabies, hepatitis B, and varicella zoster.

Common Pitfalls

- Given the importance of minimizing risk to the fetus, no medication should be prescribed unless it is clearly indicated.
- Medication exposure should be minimized by using the smallest effective dose for the shortest treatment time.
- Medications that have had extensive use and well-understood safety profiles are preferable to newer medications.
- Some medications may be safe to use in certain trimesters of pregnancy and not others.

SECTION XIV
Musculoskeletal Emergencies

Section Editor: GREGORY W. HENDEY

CHAPTER 145 Hand and Wrist Pain

Gary M. Vilke

Injuries of the hand and wrist caused by repetitive motions are most commonly associated with occupational activities. They are occurring with increasing frequency and have a tremendous economic impact on the workforce. This chapter discusses the most common of these entities.

KEY TESTING

- These conditions are diagnosed by history and exam. Laboratory and imaging are not necessary in most cases.

CLINICAL PRESENTATION

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) involves the median nerve at the wrist and is the most commonly encountered compressive peripheral neuropathy. At the wrist, the median nerve along with the flexor tendons and their sheaths pass through an anatomic tunnel that is formed dorsally by the carpal bones and volarly by the fibrous, but rigid, transverse carpal ligament. Any condition that decreases the internal diameter of the canal or increases the volume of the contents within the canal can potentially reduce capillary blood flow rates below the level which is essential for the maintenance of flow to median nerve and induce CTS. Numerous clinical conditions have been noted to cause CTS, but the disorder is most commonly idiopathic. Occupational causes include typing and

key entry jobs, repetitive use of tools, and repetitive grasping motions (1).

Females account for more than 78% of all cases of CTS, with the typical age range at diagnosis being between 40 and 60 years. The clinical presentation is often bilateral, with the patient classically complaining of numbness, tingling, burning, or paresthesias in the hand along the thumb, index, middle, and radial aspect of the ring fingers. These symptoms characteristically awaken the patient from sleep and may be relieved by shaking the hand and wrist. A nocturnal pain pattern is considered the hallmark of CTS and symptoms generally increase in frequency and intensity as the syndrome progresses. The symptoms are often exacerbated by wrist flexion, and patients may also complain of weakness or clumsiness in the hand manifested by difficulty with fine-motor functions such as picking up objects, holding items, and fastening buttons.

Guyon Canal Syndrome

Guyon canal (ulnar tunnel) syndrome involves the ulnar nerve at the level of the wrist. The ulnar nerve provides the primary motor innervation to the intrinsic muscles of the hand as well as supplying sensation for a significant portion of the hand, including the skin over the hypothenar eminence, the little finger, and the ulnar side of the ring finger. The ulnar nerve and artery pass together into the wrist on the radial side of the pisiform bone via an anatomic space called the canal of Guyon, a 4-cm-long channel located between the pisiform bone and the hook of the hamate (2).

Patients with ulnar nerve compression at the wrist typically present with wrist pain that radiates into the ulnar two digits. Fractures of the hook of the hamate have been reported to account for 14% of all cases of ulnar nerve compression in the wrist (3). As repeated blows to the ulnar side of the hand have been implicated as a cause of ulnar neuropathy at the wrist, patients should also be asked about repetitive trauma. In recent years this disorder has been reported more frequently in cyclists (4,5).

Hypothenar Hammer Syndrome

Hypothenar hammer syndrome (HHS) involves trauma to the distal ulnar artery at the base of the hypothenar eminence, just distal to the volar carpal ligament, where it is no longer protected within Guyon canal and is covered only by skin, subcutaneous fat, and, in 85% of the population, the palmaris brevis muscle (6). Given its susceptible position, the ulnar artery is easily compressed between hard objects and the hook of the hamate. Repetitive ulnar artery injury can result in traumatic vasospasm, thrombosis, or aneurysm formation (7). These can occur any time the hypothenar aspect of the base of the palm is subjected to trauma, and thus HHS is most commonly seen in those individuals who use the palms of their hands to push, pound, or hammer as part of their regular activities (7). Some examples include carpentry, baseball, Frisbee, hockey, martial arts, mountain biking, and weightlifting.

HHS is a treatable syndrome that should be considered in patients presenting with complaints of symptomatic digital ischemia. Clinical findings in HHS include a male predominance, unilateral hand involvement, and the acute onset of pain followed by a more gradual development of Raynaud phenomenon, including increased sensitivity of the digits with exposure to cold and a lack of thumb involvement (6,8). At presentation, a patient may complain of one or more episodes of acute, lancinating pain over the hypothenar eminence that occurs after striking a blow with the palm of the hand. This pain typically radiates into the fourth and fifth fingers, and a dull, aching hypothenar pain may then ensue. Other patients describe an immediate pain episode that resolves completely over time. Then, days to weeks or months later, ischemic finger symptoms develop as a consequence of a slowly progressing thrombosis of the ulnar artery (9). More severe trauma to the ulnar artery can damage the internal elastic lamella, leading to formation of intra-arterial thrombi (6). Embolization of traumatized intima and thrombus cause digital ischemia by occluding the end arterial supply to the fingers. Thrombosis involving the adventitia may

affect periarterial sympathetic fibers, resulting in vasospasm that limits surrounding collateral circulation (9).

De Quervain Tenosynovitis

De Quervain tenosynovitis (DQT) is the most common tendonitis of the extensor tendons of the hand and wrist. It is a nonsuppurative tenosynovitis of the first dorsal compartment, or "tunnel" of the wrist through which the tendons of the hand's extrinsic extensor muscles pass (10,11). This compartment overlies the styloid process of the radius and contains the tendons of the abductor pollicis longus (APL) and the extensor pollicis brevis (EPB) (10). The APL tendon inserts at the base of the dorsum of the thumb's metacarpal, and the EPB tendon inserts at the base of the thumb's proximal phalanx. At the wrist, these tendons and their synovial sheaths lie between the carpal bones and a fibrous band called the *dorsal retinaculum*. Tasks involving repeated pronation and supination of the forearm combined with forceful exertion of the thumb beyond the point of fatigue are commonly implicated in DQT, which represents a derangement in the normal gliding of the APL and/or the EPB tendons (10). Activities reportedly causing DPT include excessive writing or keyboard use, washing clothes, chopping wood, sewing, and playing the piano. Often, symptoms begin within days of starting a new job or resuming an old one after a holiday (12).

Pain at the radial styloid is a classic and defining symptom of DQT, with a history of gradual onset of pain and the absence of fracture or acute trauma (13). It typically affects women more than men (approximately 5:1 to 10:1) and presents between the ages of 35 and 55 years (12). The pain is usually severe and constant and is exacerbated by thumb abduction, ulnar deviation of the wrist, and simple grasping. Patients with advanced cases may develop swelling and crepitus. The pain may radiate proximally into the forearm or distally to the thumb and may disturb sleep. Some patients may complain of weakness or an inability to use the affected hand secondary to the pain.

DIFFERENTIAL DIAGNOSIS

Cervical nerve root irritation or compression, especially at the C6 and C7 levels, may produce numbness in the median-innervated fingers, with pain radiating to the shoulder. However, cervical root radicular pain seldom bilateral or worse at night. Pronator syndrome, which is compression of the median nerve in the proximal forearm, can present similar to CTS; however, both Phalen test and Tinel sign should be negative.

Lesions at any location along the length of the ulnar nerve or the nerve roots from which it arises can cause symptoms of wrist or hand pain. Brachial plexus pathology may also be responsible for symptoms in the distribution of the ulnar nerve. Pancoast tumor, an apical tumor of the lung, can exert pressure on or grow into the brachial plexus, resulting in symptoms distant from the primary site (14). Thoracic outlet syndrome can also result in a brachial plexopathy.

The most common location of ulnar nerve compression is in the cubital tunnel of the elbow. Most patients presenting with a combined ulnar motor and sensory finding have compression from a ganglion. Anomalous muscle bellies, lipomas, giant-cell tumors, schwannomas, thickened ligaments, bipartite hamuli, and pisiform–hamate coalitions are also responsible for ulnar nerve compression at the wrist (3,15).

Collagen vascular diseases and various vasculitides and coagulopathies may all cause poor perfusion of the hands and fingers and could be mistaken for HHS. These disorders, however, tend to be systemic and have generalized findings. Buerger disease, also known as thromboangiitis obliterans, affects primarily young males and presents with Raynaud phenomenon. However, it is found almost exclusively in cigarette smokers and often involves both upper and lower extremities, whereas HHS is usually confined to a single hand.

Radial nerve entrapment can present similarly to DQT. Recently, individuals using cell phones or other handheld communication and gaming devices are developing a painful tendonitis from overuse of

the thumbs. Some have termed this as “texting thumb,” “Game-boy thumb,” or “Blackberry thumb” (16). Intersection syndrome, another tenosynovitis of the radial extensor tendons, may be confused with DQT. Patients with this disorder typically have pain, swelling, and crepitus in a more proximal, ulnar distribution in the region where the radial wrist extensors of the second dorsal compartment and the tendons of the first dorsal compartment intersect, rather that at the radial styloid as seen in DQT (17).

ED EVALUATION

Carpal Tunnel Syndrome

Physical examination may reveal decreased sensation to light touch or decreased two-point discrimination in the median nerve distribution. Phalen wrist-flexion test and Tinel sign are frequently found to be positive in CTS but are neither sensitive nor specific (1,18,19). The *Phalen test* is considered to be positive if holding the wrist in complete, but unforced, flexion for 30 to 60 seconds reproduces or exaggerates the numbness and paresthesias in the median nerve distribution. The *Tinel sign* is positive if light tapping over the median nerve at the wrist causes a tingling sensation distally along the median nerve. In more advanced cases, there may be weakness of the median-innervated thenar muscles, the abductor pollicis brevis, and the opponens. Thenar atrophy can develop and is best seen as a guttered appearance along the radial aspect of the thenar eminence that exposes the first metacarpal.

Guyon Canal Syndrome

Physical examination of a patient complaining of a painful wrist and hand with ulnar nerve complaints must include the neck. Painful or limited range of motion may suggest the presence of cervical disc disease. This should be followed by axial compression of the cervical spine, which may elicit radicular pain from a compressed nerve root. The elbow should be examined for evidence of swelling, deformity, inflammation, or masses. The ulnar nerve should be carefully palpated and percussed to assess for increased irritability.

Careful palpation over the hook of the hamate may reveal tenderness associated with an occult new fracture or a poorly healed old fracture.

The *Allen test* performed on both hands will help the clinician to ascertain the ulnar artery's contribution to hand perfusion. The modified Allen test is performed with the patient seated with the palms facing up, resting on the knees. The clinician compresses the radial artery with one thumb and the ulnar artery with the other thumb, thereby occluding the arterial supply to the hand. The patient rapidly clenches and opens the hand several times to exsanguinate the blood from the palm. If there is pathology in the ulnar artery, the palm will remain pale after the pressure over that vessel is released. In this case, blood supply returns to the palm only after the pressure over the radial artery is removed.

In patients with Guyon canal syndrome, the examiner should be able to elicit paresthesias of the ulnar fourth and fifth digits by putting the wrists into complete volar flexion or by percussing over the ulnar nerve at the level of Guyon canal. Impaired sensation of the ulnar dorsum of the hand to both light touch and two-point discrimination with weakness of the flexor digitorum profundus (FDP) muscles of the fourth and fifth digits is suggestive of an ulnar nerve lesion proximal to its bifurcation into motor and sensory branches at the wrist.

Interosseous muscle function can be evaluated by asking the patient to cross the index and middle fingers. *Froment sign* occurs when the adductor pollicis muscle, innervated by the ulnar nerve, is weak. This sign is elicited by having the patient tightly hold a piece of paper between the thumb and the radial side of the index finger while the examiner attempts to pull the paper from the patient (Fig. 145.1). Flexion at the interphalangeal joint of the thumb, indicating weakness of the adductor pollicis muscle, is confirmatory of a positive Froment sign. Comparison should be made with the patient's other hand.

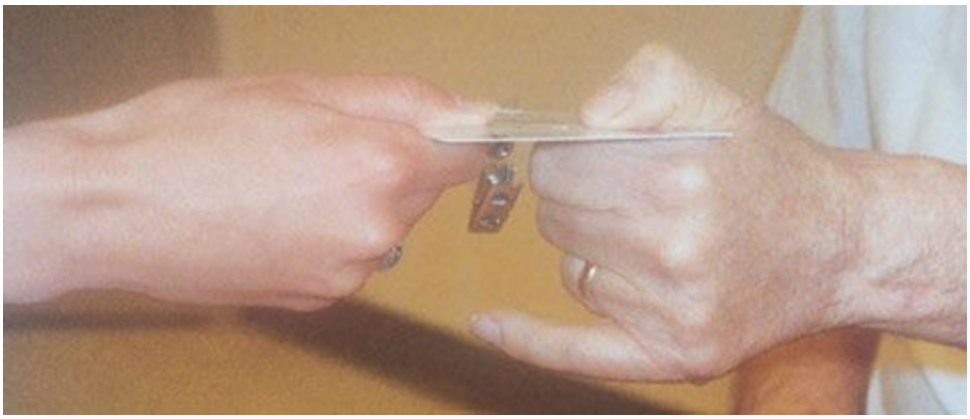

FIGURE 145.1 Froment sign. (From Berg D, Worzala K. *Atlas of Adult Physical Diagnosis*. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Hypothenar Hammer Syndrome

Physical findings in HHS are largely localized to the hypothenar eminence and the digits of the affected hand. Prominent calluses over the hypothenar eminence provide a clue about recurrent trauma to this area. Tenderness to palpation over the hypothenar area may indicate the presence of an ulnar artery aneurysm. Further examination may reveal the fingers or fingertips to be cold, pale, mottled, atrophic, or ulcerated (20). The Allen test should be performed, with a positive test suggesting ulnar artery pathology.

De Quervain Tenosynovitis

Examination of the wrist in mild cases may exhibit only subtle, localized swelling at the radial styloid (10,16). Swelling and erythema may be present in more severe cases. Tenderness or crepitus at the radial styloid is highly suggestive of DQT, with a positive Finkelstein test being diagnostic of this condition (11). The Finkelstein test requires that the patient flexes the thumb into the palm and then grasps it with the other fingers of the hand. The patient then actively ulnarly deviates the wrist (Fig. 145.2). Severe, sharp pain with this maneuver constitutes a positive test and is pathognomonic of DQT.

FIGURE 145.2 Finkelstein test.

Imaging and laboratory testing, such as radiographs, are typically not required in clinically straightforward cases of all the foregoing entities unless fracture is suspected, but cervical spine imaging may be useful if clinical symptoms suggest a cervical radiculopathy. Similarly, chest radiographs should be obtained if there is concern for an intrathoracic mass lesion causing a brachial plexopathy. Laboratory studies, in the absence of systemic clinical signs or symptoms, are unlikely to provide any useful information.

ED MANAGEMENT

Carpal Tunnel Syndrome

Wrist splints in neutral or slight extension should be utilized, particularly at night. The patient should avoid activities that aggravate symptoms, and nonsteroidal anti-inflammatory (NSAID) medications should be prescribed.

Guyon Canal Syndrome

The application of a wrist splint, avoidance of activities that aggravate symptoms, and use of NSAIDs should be initiated. Some

have studied using gloves to protect the ulnar nerve from compression during activities (4). A trial period of 1 to 3 months of nonoperative intervention is recommended; however, depending on the etiology, symptoms may or may not resolve during this time (3). The most radical treatment option is surgery to relieve tension over the volar carpal ligament to reduce nerve compression (5).

Hypothenar Hammer Syndrome

Most patients with HHS respond to proper therapy when promptly initiated (21). Local wound care of necrotic or ulcerated digits can be initiated in the emergency department (ED). The patient should be counseled to avoid cold environments and stop smoking, if applicable, and patients should wear mittens or gloves to help keep their hands and fingers warm and protected. Aspirin and low-dose calcium-channel blockers, such as diltiazem 30 mg PO qid or nifedipine 10 mg PO tid, may be prescribed as initial therapeutic agents (21). The prognosis for appropriately treated HHS is generally good, and surgery typically is not necessary. Patients must understand that response to therapy is predicated on discontinuing the repetitive trauma that is the cause.

De Quervain Tenosynovitis

Conservative treatment utilizing rest, application of heat, NSAIDs, and immobilization with a thumb spica splint is often inadequate (10,22). These modalities should be used in addition to the mainstay of treatment, which is steroid injection, a procedure that is up to 83% effective and may be performed by the ED physician (11,22).

Approximately 2 mL of a steroid preparation (Table 145.1) should be drawn up and mixed in a syringe with 0.5 mL of lidocaine. Pass a 25- or 27-gauge needle through the skin at the distal end of the first dorsal compartment. As the needle is slowly withdrawn, the steroid–lidocaine mixture should be easily injected into the tendon sheath (Fig. 145.3). Forced injection of steroids into a tendon is not desirable. A successful injection of the steroid–lidocaine mixture is indicated by the clinician's feeling the medication track distally

along the tendon sheath. Immediate relief of pain from the use of lidocaine is a good marker for appropriate placement (11). Patients should be advised that it may take several days for the steroid to begin relieving their pain and that, in the meantime, there is a possibility of a postinjection flare reaction. This painful phenomenon, sometimes seen after injection of steroids, usually resolves after a couple of days. A short course of opioid pain medications may also be necessary. Ultrasound has been used to facilitate the steroid injections with improved success rates (23).

TABLE 145.1
Corticosteroid Doses for Injection in De Quervain Tenosynovitis

Hydrocortisone 25–100 mg
Methylprednisolone 40 mg
Prednisolone suspension 20–40 mg
Triamcinolone 20 mg

FIGURE 145.3 Corticosteroid injection into the tendon sheath.

CRITICAL INTERVENTIONS

- Identify and instruct patients to stop or modify activities leading to a repetitive-use syndrome.

- Initial conservative therapy should include a period of immobilization, as well as treatment with an NSAID.

DISPOSITION

All patients with diagnosed repetitive injury disorder may be discharged with appropriate precautions and hand specialist referral. Patients with CTS may be referred back to a primary care physician for continued care and future referral to a hand surgeon if necessary. Patients with Guyon canal syndrome and mild HHS should see a hand specialist for followup for additional outpatient evaluation and treatment. In the absence of clarifying historic or physical features for HHS, referral for arteriography or arterial biopsy may be required to confirm or rule out the diagnosis of Buerger disease, which can be managed by the hand surgeon. If the patient with HHS has significant ischemic findings, consultation in the ED by the hand surgeon may be appropriate.

Patients treated with steroid injection for DQT should be advised to seek appropriate followup care with a hand surgeon for either repeat injection or consideration of surgical release if adequate relief is not achieved after the initial steroid injection.

Common Pitfalls

- Failure to perform a thorough physical examination of both upper extremities, as some abnormal findings may be physiologic and not pathologic.
- Failure to examine the entire course of the ulnar nerve from its origin at the nerve roots of the cervical spine to the hand. Ulnar neuropathy may be due to compressive forces at one or more locations along the length of the nerve.
- Failure to recognize an occluded ulnar arterial supply to the hand.
- Failure to consider and recognize HHS, which is a treatable condition, provided that the source of trauma is eliminated.

CHAPTER 146 Bursitis and Tendinopathy

Ryan Friedberg

BURSITIS

Bursitis is defined as the inflammation of a bursa. The term *bursa* comes from the Greek words “hide” or “wineskin” and the Latin meaning is that of a small leather sac or purse (1). Bursae are flattened sacs of synovial membrane that contain a viscid fluid that moistens the bursa wall to facilitate movement by minimizing friction between contiguous muscles, tendons, bones, ligaments, and skin (2,3).

There are more than 78 bursae on each side of the body, and are found where a tendon rubs against a bone, ligament, or other tendon (4,5). Fortunately, only a few of these bursae usually cause problems that would bring a patient to the emergency department (ED). The most common areas of bursitis seen in the ED are olecranon and prepatellar bursitis. This is likely due to their superficial locations. Other areas of bursitis seen in the ED include the subacromial, trochanteric, ischiogluteal, iliopsoas, pes anserine, and retrocalcaneal bursa (5,6).

Bursitis is usually divided into nonseptic and septic causes. The exact incidence of bursitis is unknown, but some studies suggest it is between 0.01% and 0.1% of ED visits and only 30% are infected (7–9). Approximately 80% of patients that present with bursitis are male and usually between the ages of 31 and 57 (7,10).

Nonseptic bursitis (eFigs. 146.1 and 146.2) is a sterile inflammation of the bursa that has been attributed to multiple causes including trauma, overuse, rheumatic, and idiopathic. Septic

bursitis (eFigs. 146.3 and 146.4), on the other hand, is an infection of the bursal sac usually caused from skin lesions secondary to trauma, but other causes include iatrogenic (needle aspiration) and idiopathic. Hematogenous seeding is a rare cause of septic bursitis (11). *Staphylococcus aureus* is the most common organism found in septic bursitis occurring in 72% to 92% of cases, but rare organisms such as *Cryptococcus neoformans* and *Aspergillus terreus* have been reported in patients that are immunocompromised or have systemic illness (12).

eFIGURE 146.1 AP View of Nonseptic Olecranon Bursitis

eFIGURE 146.2 Lateral View of Nonseptic Olecranon Bursitis

eFIGURE 146.3 AP view of septic Prepatellar Bursitis

eFIGURE 146.4 Lateral View of Septic Prepatellar Bursitis

CLINICAL PRESENTATION

Patients most commonly at risk for developing bursitis include laborers such as miners, gardeners, construction workers, and mechanics, in whom repetitive knee or elbow trauma is common (9). It is also common in athletes such as wrestlers, hockey players, rugby players, and football players where trauma to the knees and elbows are very common. Patients with bursitis, whether septic or nonseptic, present with a few common features. These include localized swelling and fluctuance of the bursa and usually painless passive range of motion of the elbow or the knee joint. Pain, although present in almost all septic bursitis patients, is also seen in about 45% of nonseptic bursitis patients. If generalized joint swelling, inflammation, and restricted range of motion are present, septic arthritis (and hence the need for an arthrocentesis) should be considered in the differential diagnosis (9).

Some features that help to differentiate a septic bursitis from a traumatic nonseptic bursitis include local pain, redness, warmth, and fever.

The most common type of bursitis seen in the ED is olecranon bursitis. This is the only bursa of the elbow joint and is on the extensor aspect over the olecranon process (9). In some outpatient series, it is more common than prepatellar bursitis by a ratio of 4:1 (13). This has been ascribed to the higher frequency of pressure damage and injury to the elbow compared to the knee.

DIFFERENTIAL DIAGNOSIS

Included in the differential diagnosis of bursitis is the consideration of arthritis (septic versus nonseptic), trauma, crystal-induced disease (such as gout, calcium pyrophospate dihydrate crystals), rheumatoid arthritis, and arthritis associated with such conditions as uremia, scleroderma, ankylosing spondylitis, pancreatitis, and SLE (6,9,14). An overlying cellulitis is also in the differential diagnosis (9). Although much less common, other bursae that have been noted to be septic include the trochanteric and subacromial bursae. Bacterial

endocarditis has been noted to be associated with trochanteric bursitis (15).

ED EVALUATION

Differentiation between septic and nonseptic bursitis is important. Historical findings are not particularly helpful in attempting to differentiate between aseptic and septic olecranon and prepatellar bursitis. A history of trauma may be seen with equal frequency in septic and nonseptic cases of bursitis (6,9). A prior history of bursitis that reflected past injury or an underlying rheumatic disease also was not found helpful in distinguishing between the two. However, the duration of symptoms before presentation is generally shorter in the patient with septic bursitis (14).

Although the gold standard for diagnosis of a septic bursitis is a culture-positive aspirate, physical findings are often helpful in the differentiation between septic and nonseptic bursitis (14). Fever is very specific to septic bursitis and almost never associated with nonseptic bursitis (6,13,15). An abrasion or laceration may be present in about half of patients with septic bursitis (9). Tenderness to touch, peribursal soft tissue inflammation, and overlying skin lesions are more commonly seen in infected bursae than in noninfected bursae. Elevation of surface temperature overlying the bursa of $>2.2^{\circ}C$ when compared to unaffected side has also shown to be very specific and sensitive in determining a septic bursa (16). Peribursal cellulitis is not uncommon in septic bursitis, and has been described at times as “so severe as to obscure the underlying bursal pathology” (6). Occasionally a concomitant effusion in a joint or tissue space adjacent to the bursa has been seen in septic bursitis (6,9). In nonseptic bursitis, a nontender bursal effusion (traumatic or idiopathic) may be present, although almost half have mild bursal tenderness.

Patients with crystal-induced bursitis show signs of acute bursal inflammation. Some may have a low-grade fever and a concurrent gouty arthritis (17,18). There have been reports of concurrent septic bursitis in patients with gouty bursitis (9).

Once the clinical diagnosis of bursitis of the olecranon or prepatellar bursa is made, aspiration and analysis of the bursal fluid may reveal the cause of inflammation (13). Although fluid analysis is the gold standard for diagnosing septic arthritis, the need to aspirate every olecranon or prepatellar bursa as part of the initial management has become controversial. Many have stated that bursal aspiration is a necessary part of the initial workup for bursitis to appropriately direct the therapy (8,9,14,19,20). The aspiration is diagnostic and can also be therapeutic. The controversy lies in the concern for the complications arising from the aspiration. The two most serious complications are infecting a nonseptic bursitis and creating a draining fistula or tract that will not heal and may become infected. Thus, some authors suggest forgoing aspiration and treating only with rest, compression, and NSAIDs if a nonseptic bursitis is suspected (6,7,14). However, the bursa should be aspirated if there is any suspicion for infection and appropriate antibiotics should be administered. When determining ED management, one should consider discussing the need to aspirate with the specialists providing subsequent treatment so the care remains consistent.

It has been recommended that if there is suspicion of an infection in an adjacent joint, any fluid collection should be analyzed when septic bursitis is diagnosed so that a septic effusion can be differentiated from a “sympathetic” effusion (6). Aspiration should be performed through skin that is not affected by cellulitis, if at all possible (6).

When aspirating a bursa, an aseptic lateral approach to the bursa using an 18- to 22-gauge needle has been described (9). It has been recommended that aspiration from the extensor side of the elbow or knee should not be done because of the potential of a higher risk of chronic fluid drainage (9). Sufficient fluid should be aspirated so as to drain the potentially infected bursa and obtain appropriate studies. The aspirate should include a white blood cell (WBC) count with differential, crystal evaluation, and culture and sensitivities (8). It has been suggested that fluid glucose and lactic acid levels be measured, since low glucose and elevated lactic acid levels may be

found in the presence of bacterial infection, but these are neither sensitive nor specific (6).

The appearance of the aspirate in septic bursitis may be purulent, straw colored, or serosanguinous. In the nonseptic bursa, the aspirate may range in appearance from straw colored to bloody (9). Although the presence of organisms on Gram stain or culture is diagnostic for septic bursitis, the WBC count is helpful in distinguishing septic from nonseptic bursitis. The Gram stain is not positive. In a nonseptic bursa, the leukocyte count is usually less than 1,500 per μL, with a predominance of mononuclear cells. It is uncommon to be more than 10,000 WBCs per μL (9). Septic bursitis is more likely to present with a higher WBC count with a predominance of polymorphonuclear cells, but a low WBC count does not rule out infection (9). Gram stains of culture-proven septic bursitis have been reported to be negative in about 30% of cases and hence cannot be used alone to exclude a septic bursitis.

Routine cultures should be done of the aspirate. Some series indicate that *S. aureus* is found in 80% to 100% of positive cultures; *Streptococcus* (group A β-hemolytic *Streptococcus* most commonly) is seen in less than 10%. *Staphylococcus epidermidis* has been cultured as well. Anaerobes, mycobacteria, fungi, *Haemophilus influenza,* and other gram-positive and gram-negative organisms have been found infrequently (6,9,20,21).

Crystal-induced bursitis, most commonly associated with gout, should reveal negatively birefringent urate crystals. Olecranon bursitis caused by calcium pyrophosphate dihydrate crystals has been reported as well. The appearance of the fluid may range from straw colored to bloody. Cell counts overlap septic and other nonseptic etiologies, ranging from 1,000 to 6,000 per μL, and concomitant gouty and septic bursitis have been reported (9). A recently injected bursal sac may contain the birefringent crystals of a long-acting steroid preparation (6).

Depending upon the history, radiographs may be indicated. Soft tissue abnormalities, such as calcifications, swelling, or gas, may be seen. Bony disruption as a result of trauma, foreign body, and other possible etiologies or associated abnormalities should be considered.

Although not common, an associated osteomyelitis has been described, and was associated with a longer delay to diagnosis from onset of symptoms (>3 weeks). Ultrasonography can be done to confirm a fluid collection, possibly detect loose bodies, rheumatoid nodules, as well as gout tophi, but cannot differentiate between septic and nonseptic bursitis (11). Computed tomography (CT) or magnetic resonance imaging (MRI) may also be indicated in specific circumstances (6,15).

KEY TESTING

- If septic bursitis is suspected, aspirate fluid for cell count, crystals, Gram stain, and culture.

ED MANAGEMENT

An inflamed olecranon or prepatellar bursa associated with a positive aspirate warrants appropriate antibiotic treatment. As discussed earlier, sometimes the determination of a "positive aspirate" is difficult to discern prior to the results of the culture due to the significant rate of false negative Gram stains and the significant overlap of cell counts in septic and nonseptic bursitis. In cases where the Gram stain is negative and the cell count is indeterminate it is recommended to start antibiotic treatment until the culture results are available. Penicillin antibiotics have been shown to achieve effective bursal concentrations when given either intravenously or orally. A 14-day course should be given. Other effective antibiotics include cefazolin IV and clindamycin PO (7). The presence of a bursal infection for more than 2 weeks before the initiation of antibiotic treatment is associated with persistently positive cultures on serial aspirations, and thus may require more prolonged therapy. Patients with a history of bursitis (septic or nonseptic), rheumatoid nodules, gouty tophi, immunocompromised with severe infection, or septic bursitis due to unusual organisms may also require a prolonged course of antibiotics (9). Empiric antibiotic therapy should include coverage for both *S. aureus* and *Streptococcus* species. Close follow-up and possible repeated

aspiration may be necessary (9). If there is no improvement with antibiotics and aspiration, bursectomy may be indicated. The determination to perform a bursectomy is usually reserved for critically ill patients, severe soft tissue complications, immunocompromised patients, refractory cases, or chronic/recurrent cases (11).

Supportive measures such as warm soaks, wound care for associated lesions, and protection of the bursa from further trauma are important. Some cases of bursitis may require surgical excision and drainage, and recovery from septic bursitis may take months (8,12).

Treatment of acute nonseptic bursitis (traumatic or idiopathic) has included initial aspiration, the utilization of compression dressings, and administration of nonsteroidal anti-inflammatory agents (9). Although steroid injections into the nonseptic bursa has been suggested by some (9), it seems prudent in the ED to await the results of cultures and arrange for follow-up rather than to initiate long-term therapy in the ED, especially in the face of a possible septic bursitis. In one series, complications of intrabursal steroid injections included skin atrophy over the bursa (20%), chronic pain associated with pressure applied to the elbow (30%), and the development of a septic bursitis (10%) (9,22). Since all patients with bursitis need close follow-up and there is some controversy as to the initial management (to aspirate or not), it is recommended that the initial management be discussed with the physician who will be following the patient.

Although controversial, it seems reasonable that for patients in whom the suspicion of septic bursitis is very low, aspiration may be avoided in favor of conservative therapy consisting of rest, compression, NSAIDs, and close follow-up. If these methods prove unsuccessful, one should consider aspiration with or without steroid injection. There have been no conclusive studies evaluating the risks and benefits of conservative management of nonseptic bursitis comparing rest, compression and NSAIDs versus aspiration.

Treatment of nonseptic bursitis in other areas of the body including the subacromial and trochanteric bursa can be managed

the same way as olecranon and prepatellar bursitis. It should be noted that complications from cortisone injection such as skin atrophy and the development of a septic bursitis are much less in the subacromial or trochanteric bursa due to the fact that they are not as superficial as the olecranon or prepatellar bursa. In the hands of a properly trained physician, a bursal injection of a steroid and lidocaine or bupivicane mixture can hasten relief, and can thus be another option in addition to NSAIDs and rest (23).

CRITICAL INTERVENTIONS

- Initiate antibiotic therapy for patients with bacterial infection

DISPOSITION

As oral antibiotics seem to provide good bursal coverage in septic bursitis, patients with a noncomplicated olecranon or prepatellar septic bursitis, and without significant comorbidity, may be discharged with appropriate follow-up. Some authors recommend at least one dose of IV antibiotics in the ED followed by outpatient antibiotics (7). It has been recommended that those with a purulent aspirate should be aspirated at 1- to 3-day intervals as long as the effusion persists (9).

Those with severe septic bursitis, purulent drainage, or other underlying medical problems should be considered for hospital admission and treatment with intravenous antibiotics. Indications for inpatient therapy include the presence of a high fever, severe bursal infection (intense peribursal cellulitis or wound infection), or systemic toxicity (9).

Common Pitfalls

- Failure to distinguish between a septic and nonseptic bursitis
- Misdiagnosis of septic arthritis as bursitis
- Failure to discern underlying bony or soft tissue pathology causing persistent symptoms
- Failure to arrange appropriate follow-up

TENDINOPATHY

Tendons are structures interposed between muscle and bone that transmit the force created within the muscle to the bone, making joint movement possible (24). They consist of collagen bundles that provide tensile strength and an extracellular matrix that, among other duties, provides structural support. The tendon is covered by the epitenon, a loose connective tissue that contains the blood, lymphatic, and nerve supply. The epitenon is surrounded by the paratenon, and the two are sometimes called the peritendon (25).

Tendinopathies have been in the past referred as “tendonitis,” which infers inflammation of the tendon. Through histopathologic studies of the disease process, it has been shown that most “tendonitis” is actually a degenerative process going on within the tendon and not an inflammatory one (25,27). Thus, the term “tendonitis” is often a misnomer, and the terms tendinopathy or tendinosis should be used. It is possible that there is an acute inflammatory reaction that occurs at the initial stages of the degenerative process, but if so, it is likely to last upto only several days and most of the pain that people present to the ED with is likely due to more chronic symptoms secondary to degenerative changes within the tendon (26).

As a rule, a history of overuse is common in many tendinopathies, and the osteotendinous junction is the most common site (26,28). This is possibly due to the fact that tendons are relatively hypovascular proximal to the tendon insertion (29). This hypovascularity may predispose the tendon to hypoxic degeneration and has been implicated in the etiology of tendinopathies (26). Participation in athletics and occupational duties that require repetitive motions have been implicated in overuse syndromes (tendinopathies) which likely stem from cumulative, repetitive microtrauma that causes degenerative tissue damage (30). Some relatively common tendinopathies discussed that may present to the ED include those of the *rotator cuff* (both noncalcific and calcific), the *biceps tendon,* the *extensor carpi radialis brevis (ECRB) tendon (lateral elbow),* the *patellar tendon,* and the *Achilles tendon* (31).

KEY TESTING

- X-rays: Can diagnose calcific tendinopathies and rule out underlying bone abnormalities.
- Ultrasound: Ultrasound has proven to be very effective in diagnosing tendinopathies.
- Physical exam: If unable to reproduce symptoms during physical exam either with palpation or provocative maneuvers then one must consider other etiologies of the pain.

CLINICAL PRESENTATION

The classic presentation of a patient presenting with a painful tendon is one of increasing pain at the site of the tendon, and often a history of an increase in the use (hence, "overuse") of the attached muscle. The pain is often related to the load. An early tendinopathy may be noted to cause discomfort early in the activity, diminish with continued activity, and then recur after the activity if it has been prolonged. Subsequent episodes may be of increased severity (30).

The pain is usually well localized and has been described as "sharp" or "severe" during the early stages, progressing to a "dull ache" in some patients. The pain usually does not radiate and can be reproduced with movement against resistance of the attached muscle. Exacerbation is caused by activity that increases the load on the tendon, and factors that relieve the discomfort may include relative rest, ice, NSAIDs, or other analgesic medications (32).

Associated systemic diseases that may cause a tendinopathy include an underlying spondyloarthropathy (e.g., psoriasis) as well as a tendinopathy related to a sexually transmitted disease (e.g., gonococcemia) or treatment with a fluoroquinolone (31,32).

Rotator Cuff Tendinopathy

Rotator cuff tendinopathy is the most common manifestation of what has been described as the subacromial pain syndrome (SPS) (36). The rotator cuff consists of a set of four muscles (supraspinatus,

infraspinatus, teres minor, and subscapularis) which, with the deltoid muscle, enables the arm to be positioned in the overhead position. The rotator cuff muscles, anchored on the scapula, pass beneath the coracoacromial arch. Diminished space as a result of anatomy, swelling, or trauma may cause the classic presentation of rotator cuff tendinopathy by causing impingement of the supraspinatus tendon against the anterior inferior aspect of the acromion or the coracoacromial ligament. An external rotator of the humerus as well, the supraspinatus tendon, assists the deltoid in abducting the arm, with its greatest contribution being the initiation of abduction (36). The impingement injury has three stages. The first is edema and hemorrhage. As impingement becomes repetitive, fibrosis and thickening of the subacromial bursa with tendinopathy in the supraspinatus occurs. The third stage represents a tear of the tendon, either partial or complete (37).

The clinical presentation of rotator cuff tendinopathy (or tear) includes pain, weakness, and decreased range of motion. Pain is noted in the anterior, superior, and lateral aspects of the shoulder. Acute tendinopathy may be associated with mild pain when attempting to do overhead activities. As the tendinopathy becomes more persistent, the pain may occur at rest and increase with overhead activities. As there is progression to a partial- or full-thickness tear, there may be persistent pain at rest and pain at night. There may be weakness and limited active range of motion (37).

With *calcific tendinopathy,* deposition of calcium hydroxyapatite crystals in the tendon is seen through ultrasound or radiographically. Bilateral involvement is not uncommon (38). However, up to 20% of adults with no shoulder pain may have evidence of calcification of the rotator cuff tendon (38,39). Patients may complain of variable degrees of pain, either at rest or on movement. Discomfort at night and a “catching” on movement have been described (38). Pathophysiologically, the rotator cuff tendon goes through several stages, beginning with an asymptomatic fibrocartilaginous transformation, which is followed by the development of calcification within the cuff. The next stage (resorptive) is described as the most incapacitating as there is

formation of crystals that may cause severe pain and restriction of movement. Some patients may have systemic symptoms including fever and malaise, and may have an elevated erythrocyte sedimentation rate and neutrophilia. In such cases, the differential diagnosis includes gout and a septic joint. This stage may last for 2 weeks. The final stage involves healing and repair of the rotator cuff, associated with some residual pain and restriction of movement. Specific tenderness over the greater tuberosity and symptoms similar to the impingement syndrome may be seen (39).

Biceps Tendinopathy

A similar tendinopathy to that of the rotator cuff, especially seen in those with overhead activities and impingement, is that of the biceps tendon. It may occur either with rotator cuff symptoms or independently. Most cases of bicipital tendinopathy are believed to be secondary to impingement (40). Patients may have anterior shoulder pain (at the bicipital groove) that is exacerbated with supination and pronation, and on palpation have pain at the bicipital groove.

Lateral Elbow Tendinopathy (Tennis Elbow)

Tennis elbow is reflective of tendon overuse and failed healing. Initial signs and symptoms include activity-related discomfort followed by pain at rest after pathologic changes become more extensive (28). Palpable tenderness over the lateral elbow (lateral epicondyle) may be present in the early stages. Pain of the lateral elbow caused by extensor involvement is not uncommon, often seen in those who play racquet sports (tennis elbow). This is seen with eccentric overuse of the forearm extensors (e.g., backhand) (41). Pain with manual stress testing including extension of the wrist and supination of the forearm usually confirms the site of the lesion (28). Tennis elbow has been described as primarily involving the ECRB and secondarily the extensor digitorum communis (28,41). Pain with extension of the middle finger against resistance may cause pain over the insertion of the ECRB over the lateral elbow.

Patellar Tendinopathy

The knee pain of patellar tendinopathy may have an insidious onset, and is often ascribed to an activity involving jumping, or an episode of exercise that is related to a heavy training session. The patient complains of pain usually localized to an area over the anterior knee region, often complaining of tenderness at the inferior pole of the patella. Pain is often exacerbated by climbing stairs and prolonged sitting. As is not uncommon early in the course of a tendinopathy, discomfort may ease completely with exercise, progressing to the point of discomfort at rest (43).

Achilles Tendinopathy

Achilles tendinopathy is common among adult runners, with a higher incidence as age increases. The etiology is usually multifactorial (i.e., overuse, improper technique, anatomic misalignment, improper footwear, and weakness) (26). Pain is usually proximal to the insertion at the calcaneus, but can extend up to the musculotendinous junction. Physical examination often reveals a thickened, tender tendon.

DIFFERENTIAL DIAGNOSIS

Depending upon the location of pain, the differential diagnosis of various tendinopathies should include fracture, bursitis, arthritis, muscle strain, ligamentous sprains, and referred pain. Apparent rotator cuff symptoms may represent pain referred from the cervical spine, pain from the AC joint, osteolysis of the distal clavicle, or other shoulder pathology (e.g., instability, labral tear, etc.). Other potential etiologies to be considered are referred cardiac pain or intrabdominal injury such as gall bladder disease or splenic injury.

The differential diagnosis of *tennis elbow* also includes posterior interosseus nerve entrapment (motor component of the radial nerve in the forearm). The clinical manifestations of this neuropraxia include diffuse pain and tenderness along the track of the radial nerve in the extensor mass of the proximal forearm (28). Synovitis, plica, chondromalacia, and adolescent osteochondral defect (OCD)

are also in the differential diagnosis. Lateral elbow discomfort may also be associated with referred pain from the cervical spine (28,31).

Patellar tendinopathy must be differentiated from patellofemoral pain syndrome, especially in the athlete who participates in jumping sports. However, the clinical features are generally distinctive (43). Lesions of the quadriceps (e.g., tear), patellar lesions, and the possibility of rupture may also be considered.

ED EVALUATION

A thorough history and directed physical examination is important in the evaluation of the patient who presents to the ED with a tendinopathy. Imaging of tendinopathies may be accomplished with the use of radiographs, diagnostic ultrasound, and MRI (31,44). Radiographs can pick up calcific tendinopathies as well as evaluate for bony abnormalities (i.e., hooked acromium) that can predispose one to developing a tendinopathy. The use of bedside ultrasound has become very common among ED physicians, and can be very helpful in confirming the diagnosis of a tendinopathy. The use of ultrasound for diagnosis of tendinosis has proven to be a specific, but not sensitive test (33–35). The use of MRI to evaluate for tendinosis is much more sensitive and specific, but since a tendinopathy is not a true emergency, MRI should not be part of the initial ED evaluation. Other imaging techniques as indicated (e.g., radiography, CT, bone scan) may be useful in ruling out other possibilities in the differential diagnosis.

In *rotator cuff tendinopathy,* physical examination may reveal signs of impingement or a tear. The supraspinatus, the most common rotator cuff component exhibiting a tendinopathy, may be examined by resistance testing. In an attempt to isolate the supraspinatus, the arms are abducted 90° in the scapular plane (30° anterior to the coronal plane). The arms are internally rotated so that the thumbs point downward. A downward force is placed on the arms, while the patient attempts to resist by maintaining the arms parallel to the floor. An inability to resist the force is an indication of isolated

supraspinatus weakness (37). With advanced impingement and a full thickness rotator cuff tear, the patient may be unable to abduct the arm, and on examination may be unable to maintain the arm in an abducted position after the examiner places it there. This is the drop arm sign (36).

The impingement sign described by Neer consists of forward flexing the fully internally rotated arm, causing the greater tuberosity of the humerus to impinge upon the anterior and inferior surface of the acromium. An abnormal test is indicated by pain. The examiner should fully flex the patient's shoulder to 180°. If pain is produced at the end range of the arc, it is considered to be positive. Testing of the infraspinatus and teres minor is done by having the patient place the arms to the side, flex the elbow, and attempt to externally rotate against resistance (37). With long-standing disease, range of motion may be limited. The subsequent development of adhesive capsulitis may make the diagnosis of impingement more difficult (36).

In patients with suspected *bicipital tendinopathy, speed test* is performed by having the elbow extended and the forearm supinated. The examiner then resists forward flexion of the adducted shoulder. Pain that radiates to the bicipital groove is a positive test (40). *Yergason test* is performed by having the patient flex the elbow to 90° with the arm at the side. The patient is asked to supinate forcefully against resistance. Pain referred to the bicipital groove with resisted supination of the forearm is a positive test (40).

Patients with *patellar tendinopathy* are often tender to palpation of the patellar tendon attachment at the inferior pole of the patella. Tenderness is generally elicited on the deep surface of the proximal attachment of the patellar tendon when the knee is flexed at 30° with the quadriceps muscle in total relaxation (45). Depending upon the chronicity of the condition, quadriceps wasting may be seen (43). Although mild tenderness may be a normal finding in active athletes, moderate and severe tenderness have been noted to be associated with ultrasonographic evidence of tendinopathy. Pain may also be reproduced with the decline squat test, which places a

greater load on the patellar tendon than does a squat on level ground (43).

Lateral epicondylitis (tennis elbow) usually presents with reproducible pain over the extensor tendons of the forearm as they originate from the lateral epicondyle. Extension of the wrist and supination of the forearm against resistance often reproduces the pain. If a patient presents with pain over the medial epicondyle and pain with wrist flexion and pronation, one must think of medial epicondylitis (golfer's elbow) as a leading diagnosis.

Achilles tendinopathy is often easy to diagnose as the Achilles tendon is usually easy to palpate. Patients usually present with posterior heel pain, just proximal to the insertion. Often times, one can appreciate a thickened and tender tendon with palpable nodules (26).

Diagnostic imaging in the ED, if indicated, may include radiographs of the affected location. A routine shoulder series should include an anteroposterior (AP) view with both internal and external rotation of the humerus. An axillary view will permit better visualization of the glenohumeral joint, the glenoid margin, and the acromion. A scapular Y-view assesses the anterior slope of the acromion (37). Ultrasonography and MRI have been utilized in the evaluation of the rotator cuff (37). The diagnosis of *calcific tendinopathy* is confirmed by radiographs that show calcium restricted to the tendon without affecting the bone. Patients with *bicipital tendinopathy* may show signs of impingement or spurs in the bicipital groove (40). Up to 20% of patients with *lateral elbow tendinopathy* may exhibit tendon calcification or a reactive exostosis at the tip of the lateral epicondyle (42). Like with the other tendinopathies, radiographs for Achilles tendinopathy can yield calcifications in the tendon as well as spurring off the calcaneus.

ED MANAGEMENT

Treatment of the tendinopathy necessitates a long-term plan which usually should include a supervised program of physical therapy. A tendinopathy may take from weeks to months to heal. Depending

upon the circumstances, protection, rest, ice, compression, elevation, and medication have been advised (41). In the ED, along with rest from the inciting activity, the patient may be prescribed an NSAID for pain relief. The efficacy of NSAIDs as a treatment for "inflammation" in the tendinopathies has been questioned, given the paucity of data for the occurrence of inflammation seen. In fact, the analgesic effect of NSAIDs may permit patients to ignore the early symptoms of tendinopathy (31). Some authors have suggested that NSAIDs could benefit patients with tendinosis via alternate mechanisms such as accelerated formation of cross-linkages between collagen fibers (46,47). Cryotherapy has also been suggested as an effective modality (41,44) theoretically slowing the metabolic rate of tissue and possibly decreasing the extravasation of blood and protein from the new capillaries formed during tendinosis (26).

Some have advocated injection of a corticosteroid. However, given the potential complications of steroid injections (including the possible injection of steroid into the tendon and hence a loss of tensile strength and spontaneous rupture), it seems prudent to pursue other treatment options as the initial management (relative rest, ice, physical therapy). If these other treatments fail, then corticosteroid injection could be considered. Thus, it is not advocated for corticosteroid injection to be part of the initial ED management of a tendinopathy, and that it is necessary for the ED physician to arrange appropriate follow-up for these patients. Should nonoperative treatment fail, surgical options may be indicated (36,37).

Treatment of *calcific tendinopathy* includes control of pain and maintenance of function. The acute phase may require rest of the affected arm in a sling (beware, however, of adhesive capsulitis, i.e., "frozen shoulder"). Pain may be controlled with aspirin, NSAIDs, acetaminophen or ice (38). Corticosteroid injection is controversial in the acute phase, as it has been argued that it may inhibit the resorptive process. Others have advocated its use, especially when the rotator cuff impinges on the undersurface of the acromium as a result of inflammation (38). Fluoroscopically guided needle lavage in the resorptive phase, performed in the operating room or

radiology suite, has been noted to be effective (39). The use of ultrasound as well as extracorporeal shock wave therapy (ESWT) have also been studied as therapeutic modalities (38,39). Arthroscopic surgery may also be required (39).

Load reduction and relative rest are keys to management of a *patellar tendinopathy*. Complete immobilization is contraindicated as the tensile load stimulates collagen production and directs the alignment. Cryotherapy (i.e., ice) may also be effective in the treatment of patellar tendinopathy.

Relative rest, NSAIDs, and ice are also mainstay treatments for the initial management of lateral epicondylitis and Achilles tendinopathy.

For all patients suffering from tendinopathies, appropriate follow-up should be recommended. There are many different types of treatment options that have been studied with varying degrees of success. These options are usually not prescribed by the ED physician, but rather by the specialist or the patient's primary physician. They include physical therapy focusing on eccentric muscle strengthening as well as the use of modalities such as ultrasound, iontophoresis and phonophoresis, deep tissue massage, ESWT, orthotics and braces, and corticosteroid injection (26). If nonoperative treatment fails, surgery can prove very successful in certain cases and usually involves debridement of the unhealthy tendon.

CRITICAL INTERVENTIONS

- Advise initial conservative therapy for patients with a tendinopathy, including rest, ice, and an NSAID.
- Identify patients with calcific tendinopathy, as they are at risk for capsulitis.

DISPOSITION

Given the potential chronicity of a tendinopathy, the need for appropriate patient education, physical therapy, and the potential

need for surgical intervention, it is important to arrange appropriate outpatient follow-up.

Common Pitfalls

- Underestimation of the potentially long time required for healing.
- Failure to consider other entities that may present with similar findings (e.g., MI, splenic rupture, stress fracture).
- Discharge without an appropriate follow-up plan.
- Excessive or prolonged splinting or bracing (e.g., shoulder sling, knee immobilizer), which can lead to capsulitis of the shoulder or stiffness of the knee.

CHAPTER 147
Hand Infections

Carl R. Chudnofsky and Melanie Loewenthal

ESSENTIAL ANATOMY

The nail plate inserts into a depression on the dorsum of the finger called the *proximal nail fold,* which divides the proximal nail fold into superficial and deep epithelial surfaces called the *dorsal roof* and *ventral floor,* respectively. The eponychium, commonly called the *cuticle,* is a horny layer extension of the proximal nail fold that extends a short distance onto the dorsum of the nail. It seals the potential space between the nail plate and the proximal nail fold. Laterally, the proximal nail fold is continuous on either side with the lateral nail folds or paronychium. The soft tissue under the distal free edge of the nail is called the hyponychium (Fig. 147.1).

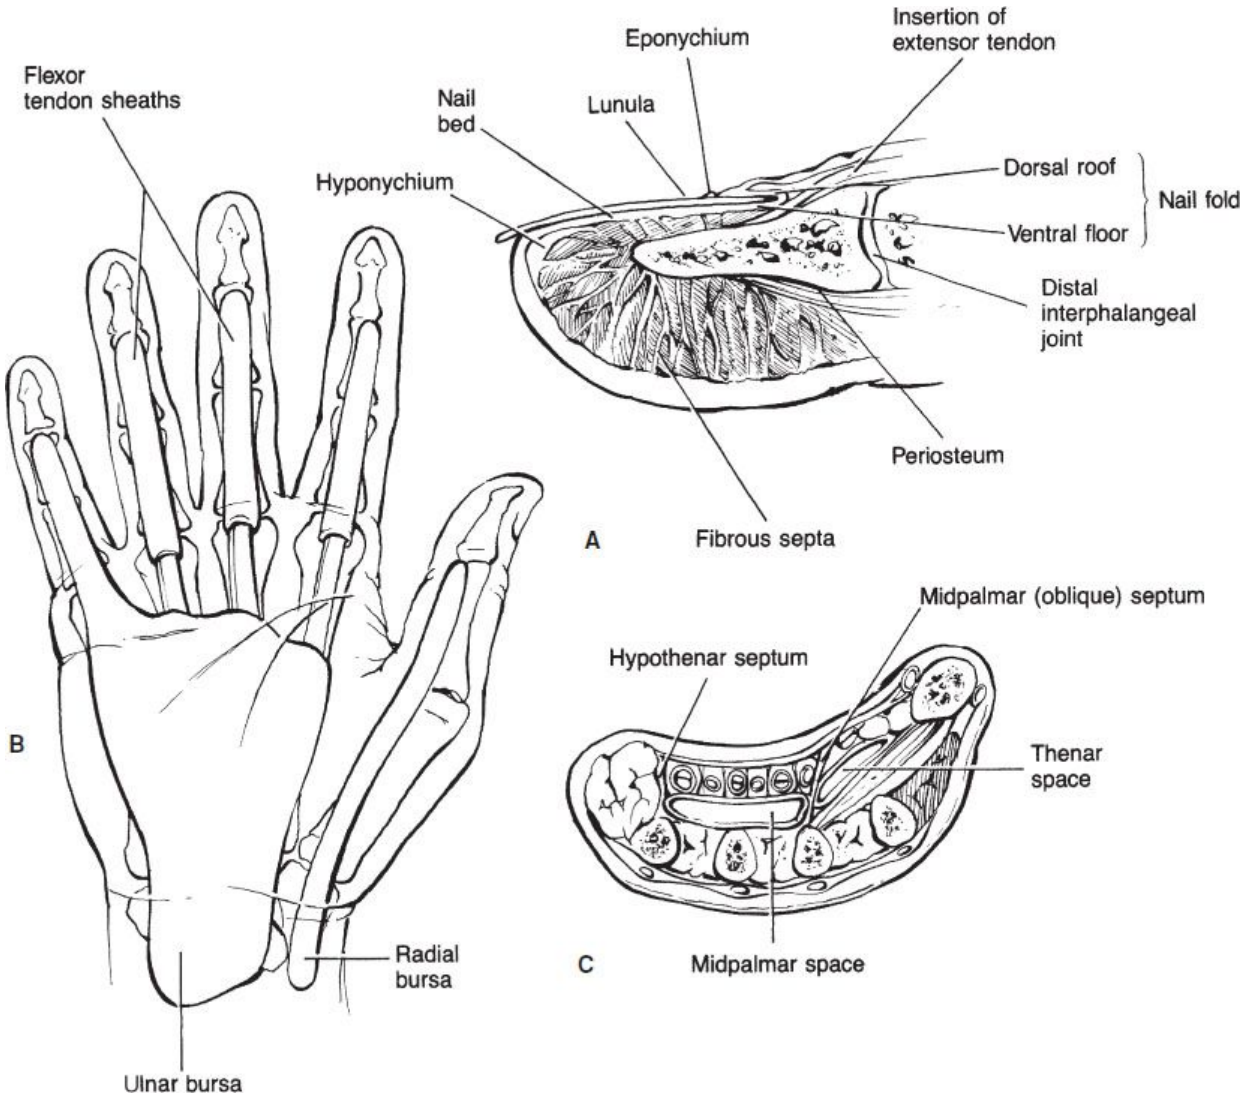

FIGURE 147.1 Anatomy. **A:** Fingertip and nail bed. **B:** Flexor tendon sheaths. **C:** Deep palmar spaces.

The distal pulp space of a finger or thumb is composed of fat globules that are divided into small fascial compartments by 15 to 20 vertical fibrous septa. The presence of these compartments has a substantial impact on the pathophysiology and management of pulp space infections (see “Felon”).

The flexor tendons are surrounded by a tendon sheath that is composed of an outer fibrous sheath and an inner synovial sheath. The inner synovial sheath has a visceral and parietal layer with a potential space between them. The tendon sheaths of the index, middle, and ring fingers extend from the midpalmar crease to just

beyond the distal interphalangeal joints. The tendon sheath of the flexor pollicis longus tendon begins at the base of the distal phalanx of the thumb and extends to the pronator quadratus muscle in the wrist. Between the base of the thumb metacarpal and the wrist, the tendon sheath of the flexor pollicis longus tendon is called the *radial bursa.* The tendon sheath surrounding the flexor tendons of the little finger begin just distal to the distal interphalangeal joint and, like the tendon sheath of the flexor pollicis longus tendon, ends at the pronator quadratus muscle in the wrist. The ulnar bursa is that part of the tendon sheath between the fifth metacarpal and the pronator quadratus muscle (Fig. 147.1). The radial and ulnar bursae communicate with each other in up to 80% of patients (1).

The hand contains several fascial spaces that are potential sites of infection. The most frequently infected spaces are the deep palmar spaces, which include the thenar space, midpalmar space, hypothenar space, Parona's space, and the web spaces. The *thenar space* is bounded on its ulnar side by the vertical septum between the third metacarpal and the long finger profundus and, radially, by the lateral edge of the adductor pollicis. The adductor pollicis also forms the dorsal roof of the compartment. The *midpalmar space* lies deep into the flexor tendons. Radially, it is bordered by the vertical septum between the third metacarpal and the long finger profundus and ulnarly by the hypothenar muscles. The dorsal roof is formed by the fascia over lying the second and the third palmar interossei and the third and fourth metacarpals. The *hypothenar space* contains the hypothenar muscles. It is bordered radially by a fibrous septum from the fifth metacarpal to the palmar fascia. *Parona's space* communicates with the hand via the carpal tunnel and is responsible for allowing infections of the hand to propagate into the forearm. This space is bordered palmarly by the flexor tendons, dorsally by the fascia overlying the pronator quadrates, radially by the flexor carpi radialis, and ulnarly by the flexor carpi ulnaris.

The majority of hand infections are caused by *Staphylococcus aureus* and *Streptococcus* species. The prevalence of community-acquired MRSA (CA-MRSA) has continued to rise in recent years, leading to an increase in CA-MRSA hand infections (2). In fact,

multiple studies since 2007 have found that the majority of hand infections are now caused by CA-MRSA (3–8). It is also important to note that intravenous drug abuse continues to be the most significant risk factor for CA-MRSA hand infections; other risk factors include infections of the digital pulp space (i.e., a Felon) and a history of a prior hand infection (2,9).

Polymicrobial infections are also increasingly common, with a prevalence reported as high 19% (10). Diabetics, patients with farm injuries, bite wounds, immunocompromised hosts and patients with a history of intravenous drug abuse are at particular risk (1,10). Anaerobes are noted in approximately 30% of all hand infections and in 40% of infections secondary to human bite or clenched-fist injuries and intravenous drug abuse (11). Gram-negative organisms are rare in normal hosts but are common in patients with diabetes mellitus or a depressed immune system (12).

Chronic hand infections may be caused by atypical mycobacteria, particularly *Mycobacterium marinum,* a common cause of hand infections occurring in aquatic environments. Sporotrichosis is a subcutaneous infection caused by *Sporothrix schenckii* (13). It usually involves the upper extremity, and is the most common subcutaneous fungal infection. Immunocompromised patients may be infected with a variety of fungi, including *Candida albicans, Coccidioides immitis, Cryptococcus,* and *Aspergillus* (14–16).

A careful and detailed history and physical examination are essential for the diagnosis and management of hand infections. A history of trauma, especially penetrating trauma, is frequently present in patients with a hand infection. The type of trauma and the setting in which that trauma has occurred can provide valuable clues to the causative organism. Cat bites are commonly infected with *Pasteurella multocida,* and infected human bite wounds or clenched-fist injuries are frequently caused by *Eikenella corrodens* and other oral flora (11). The progression of symptoms may also be helpful in determining the type of bacteria present. Streptococcal infections evolve over 24 to 48 hours and are more often associated with cellulitis and lymphangitis. In contrast, *S. aureus* is more likely to

cause a suppurative infection that develops over 3 to 6 days. Chronic infections are more often due to fungi or atypical mycobacteria (1).

Associated symptoms may aid in gauging the severity of infection and the choice of initial antimicrobial therapy. For example, a urethral or endocervical discharge in a patient with a suspected flexor tenosynovitis suggests disseminated gonorrhea. Finally, the presence of underlying medical problems (e.g., diabetes mellitus, cancer, acquired immunodeficiency syndrome [AIDS]), intravenous drug abuse, and the use of certain medications, particularly immunosuppressive agents (e.g., steroids), frequently have a significant impact on the diagnosis, treatment, and microbiology of hand infections.

The position of the hand and fingers at rest and the presence of any wounds should be noted. The location and nature of swelling, fluctuance, erythema, warmth, or tenderness should be carefully documented. The hand and individual digits should be put through a full range of motion. A thorough and well-documented neurovascular assessment is essential.

PARONYCHIA

A paronychia is an infection involving the lateral nail fold (paronychium). It is the most common infection of the hand (17). It results from mechanical separation of the eponychium from the nail plate with subsequent invasion of bacteria or fungi. Common risk factors for a paronychia include hangnails, manicures, and nail biting (1). Individuals whose hands are repeatedly submerged in water (e.g., dishwashers) seem to be particularly susceptible (18). Extension of the infection to involve the adjacent eponychium and proximal nail fold is called an *eponychia.*

The *clinical presentation* of an acute paronychia includes pain, swelling, and redness along the lateral nail fold in the area adjacent to the eponychium. If ignored or untreated, it may extend to involve the eponychium and proximal nail fold (i.e., eponychia) or, rarely, to the lateral nail fold on the opposite side (i.e., run-around infection). The involved tissue is usually very tender. Fluctuance is generally present but may be absent early in the course of the infection. In

severe infections, pus may extend beneath the nail; large amounts of subungual pus may result in a floating nail.

A chronic paronychia is a more indolent infection, often involving mixed flora or fungal organisms, especially *C. albicans.* However, it is not clear whether Candida plays an infectious role or is a frequent colonizer in an inflammatory process (18). Individuals whose hands are repeatedly exposed to water containing irritants or alkalis (e.g., dishwashers, bartenders) and those with diabetes seem to be most at risk. Patients usually complain of a waxing and waning infection with periods of acute exacerbation (1). Pain and tenderness are usually less severe in comparison to an acute paronychia.

The *differential diagnosis* for paronychia includes herpetic whitlow, a felon, and certain malignancies such as squamous cell carcinoma of the nail, malignant melanoma, and metastases from malignant tumors (19,20). Psoriasis and Reiter syndrome involving the proximal nail fold may also mimic a paronychia (18). Herpetic whitlow is a viral infection caused by the herpes simplex virus. It can usually be differentiated from a paronychia by careful history and physical examination. A severe paronychia may be confused with a felon. However, rather than subungual pus or fluctuance along the nail fold, patients with a felon will have tense swelling of the distal pulp space.

ED evaluation is usually limited to the history and physical examination. Radiographs may be useful in selected situations (e.g., a history of trauma, suspicion of a foreign body), but are generally not helpful. Laboratory testing is unnecessary in the majority of patients.

ED management depends on the severity of infection. If the diagnosis of an acute paronychia is made before the accumulation of pus, management includes an oral antibiotic effective against CA-MRSA, methicillin-sensitive *S. aureus,* and *Streptococcus* species (Table 147.1), along with warm soaks. Rest and elevation of the affected hand are helpful adjuncts. Once purulent drainage or fluctuance is noted, surgical drainage must be performed.

TABLE 147.1
Recommendations for Initial Antimicrobial Therapy of Hand Infections[a]

Infection	Initial Antimicrobial Therapy[b]	Comments
Felon/paronychia outpatient	Trimethoprim/sulfamethoxazole one DS tablet bid for 10 d	Clindamycin 150–300 mg qid for 10 d is also considered a first-line agent
Severe infections[c]	Vancomycin 1 g IV or Clindamycin 300–600 mg IV	Ceftriaxone 1 g IV is given for flexor tenosynovitis due to disseminated gonorrhea.
Diabetic/immunocompromised patients	Vancomycin 1 g IV and Piperacillin/tazobactam 3.375 g or aztreonam 1–2 g IV	High incidence of gram-negative organisms
Intravenous drug abuser	Vancomycin 1 g IV	High incidence of methicillin-resistant *Staphylococcus aureus*
Herpetic whitlow	None	Acyclovir for suppression of recurrent attacks and for severe infection in immunocompromised patients

[a]Agents or a combination of agents with similar coverage may be substituted. Alternatives for penicillin- and/or cephalosporin-allergic patients are discussed in the text.
[b]Initial antimicrobial therapy should be adjusted as the results of culture and sensitivity tests become available.
[c]Flexor tenosynovitis, web space abscess, and palmer space infection.

A digital block provides adequate anesthesia for drainage. Prior to drainage, clean the affected digit with povidone–iodine or a similar agent and place a 1-in Penrose drain securely around the proximal portion of the digit to maintain hemostasis.

To drain superficial infections, insert a no. 11 blade between the nail and eponychium lifting the eponychium away from the nail to drain the pus (Fig. 147.2). If necessary, the blade can then be swept around to incise the lateral nail fold. Make the incision tangential to the dorsolateral curve of the nail, with the blade directed away from

the nail bed and nail matrix to avoid injury to these structures. After drainage, insert a small gauze wick between the eponychium and nail to facilitate continued drainage.

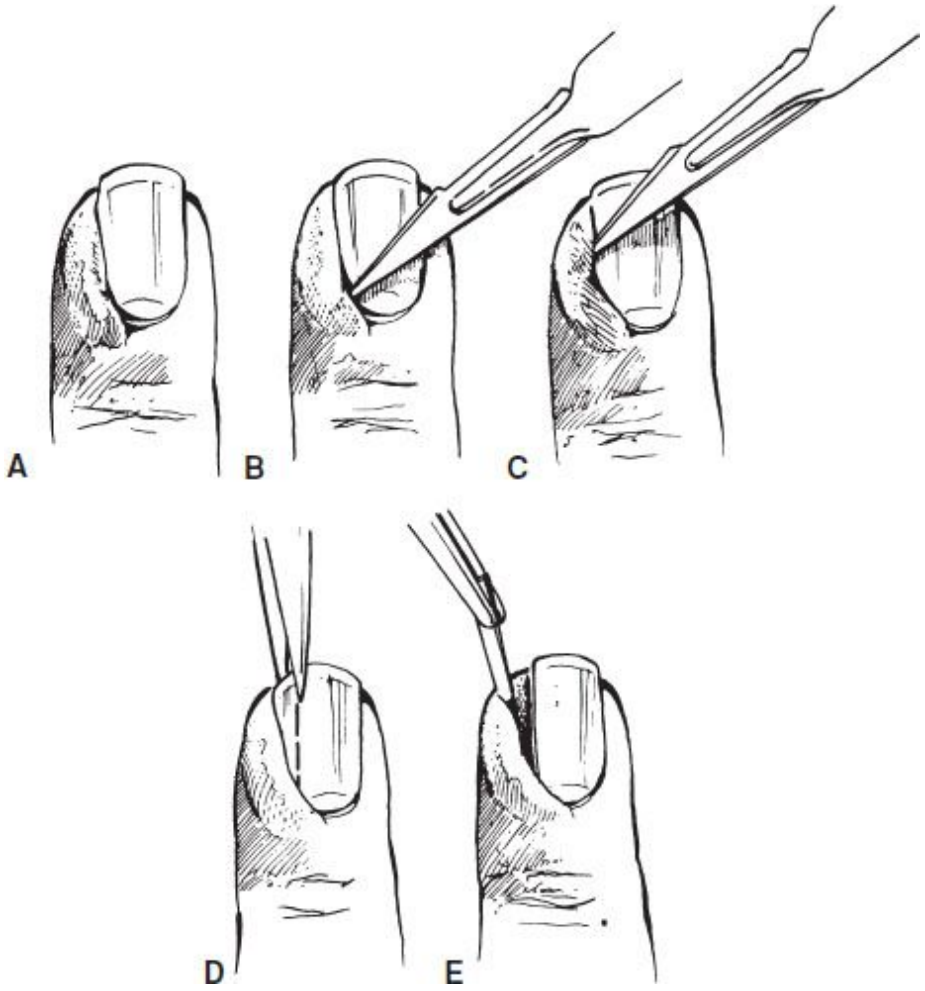

FIGURE 147.2 Drainage of a paronychia. **A:** Superficial paronychia. **B:** Elevation of the eponychia using a no. 11 blade. **C:** If necessary, the lateral nail fold may be incised to achieve adequate drainage. **D:** A more extensive paronychia with pus extending under the adjacent portion of the nail. **E:** Removal of the adjacent one-fourth of the nail to drain the subungual pus. If removal of the nail does not allow complete drainage, the lateral nail fold may be incised as in **(C)**.

If pus is present under the adjacent portion of the nail, remove one-fourth of the nail on that side to allow adequate drainage to occur (see Fig. 147.2). First separate the portion of nail to be

removed from the underlying nail bed by inserting a small hemostat or iris scissors beneath the distal free edge of the nail and gently open and close the instrument while working it proximally toward the eponychium. Once the nail is separated, use iris scissors to cut longitudinally along the nail from the distal edge to the eponychium. Finally, gently remove the nail with the aid of a Kelly clamp. If this does not allow complete drainage of pus, make an incision into the lateral nail fold as previously described and insert a gauze wick to promote continued drainage. If pus is discovered under the dorsal roof of the proximal nail fold or beneath the nail in the nail fold or if the patient presents with a floating nail, drainage requires removal of the proximal one-third of the nail.

If the infection involves the eponychium and one lateral nail fold (in addition to pus under the dorsal roof or nail root), Siegel and Gelberman (21) recommend making a single incision starting at the midpoint of the lateral nail fold and extending it proximally to the base of the nail. Bluntly elevate the eponychial tissue and lateral nail fold from the nail and remove the proximal one-third of the nail using an iris scissors (Fig. 147.3). If a run-around infection is present, make an incision in each lateral nail fold as just described. Gently elevate the entire eponychium as a flap to expose the underlying nail root, and excise the proximal one-third of the nail using iris scissors.

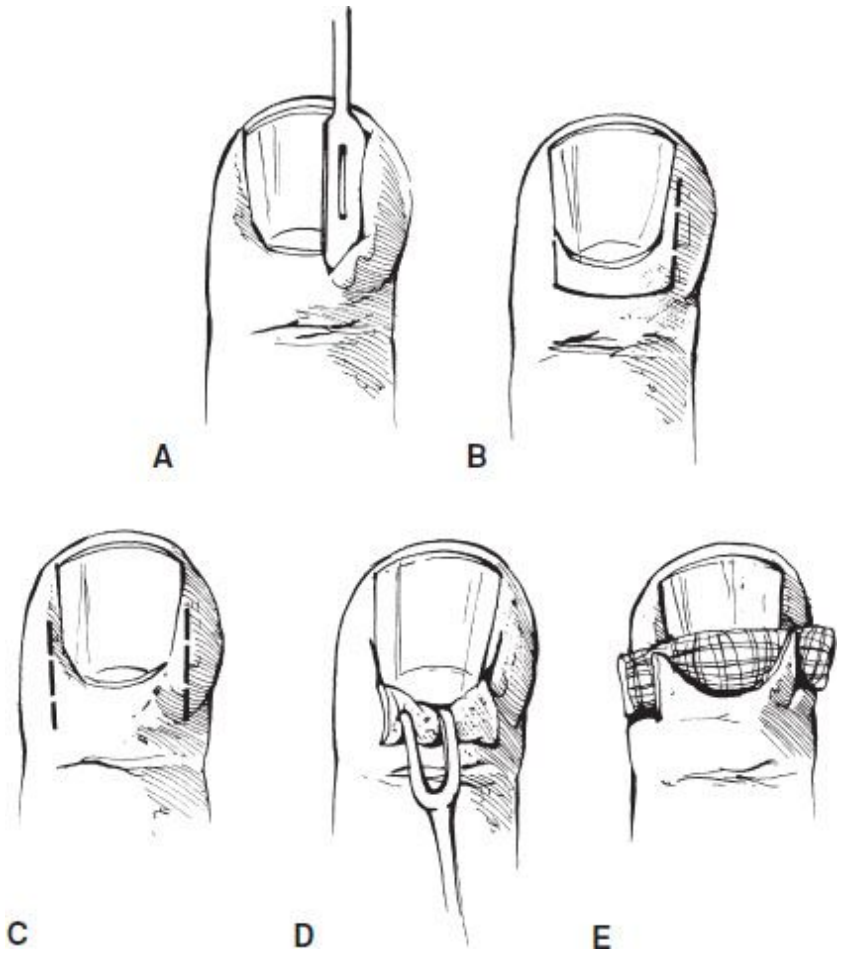

FIGURE 147.3 Drainage of a paronychia associated with a floating nail or with pus beneath either the dorsal roof of the proximal nail fold or the nail within the proximal nail fold. **A:** Elevation of the eponychial fold with a flat probe to expose the base of the nail for excision of a floating nail. **B:** Placement of an incision to drain the eponychium and lateral nail fold and to elevate the eponychial fold for excision of the proximal one third of the nail. **C–E:** Incisions and procedure for elevating the entire eponychial fold for excision of the proximal one-third of the nail. A gauze pack prevents premature closure of the cavity. (Redrawn from Neviaser RJ. Infections. In: Green DP, ed. *Operative Hand Surgery*, 3rd ed. New York, NY: Churchill Livingstone; 1993:1023.)

Some authors are reluctant to incise the eponychium for fear that the eponychial tissue will not heal primarily in the face of infection and that the incision may result in a notch or square corner in the

eponychium (22). Unfortunately, there are few scientific data regarding the optimal approach. If a floating nail is present, incision of the eponychial tissue is probably unnecessary because removal of the nail can be easily performed by pushing back the lateral nail fold and excising the loose nail (Fig. 147.3). Regardless of which technique is used, after removal of the proximal portion of the nail, insert a gauze wick between the eponychium and exposed nail to prevent adhesion of the eponychium to the nail bed and to facilitate continued drainage.

The treatment of a chronic paronychia is much more difficult. Reducing exposure to moist environments and chemical irritatants is clearly beneficial. Initial treatment with a combination of antifungals and topical steroids (e.g., 3% clioquinol in triamcinolone–nystatin mixture) should be considered, but frequently, surgical debridement with nail plate removal is needed (1).

The majority of patients with a paronychia may be discharged from the ED. Instruct the patient to keep the affected digit clean and dry and to elevate the hand to reduce pain and swelling. Patients with a small superficial paronychia should remove the gauze packing after 24 hours and begin warm soaks. Larger, more extensive infections should be checked at 48 hours. If the infection appears to be healing, remove the packing material and start the patient on warm soaks. An oral antibiotic should be prescribed (Table 147.1). The need for admission is rare, but should be considered for those patients who have an extensive surrounding cellulitis or lymphangitis, particularly in high-risk individuals (e.g., diabetics, immunocompromised patients). Consultation with a hand surgeon is recommended for high-risk patients with a severe infection.

Common Pitfalls

- Failing to recognize the need for surgical drainage. If the presence of pus is suspected, drainage should be performed.
- Failing to remove the adjacent portion of the nail when subungual pus is present. This may result in inadequate drainage.
- Failing to place a wick between the eponychium and nail plate after drainage. This may result in reaccumulation of pus and, if

the proximal portion of the nail was removed, adhesions between the eponychium and underlying nail bed.

FELON

A felon is an infection of the distal pulp space of a finger or thumb. It occurs more commonly in the right hand, with the thumb and index finger most frequently affected. The infection frequently results from a puncture wound to the tip of the digit. A subcutaneous abscess rapidly forms in the pulp space, breaking down the fibrous septa as it expands. Because the fibrous septa create a closed space within the fingertip, pressure from the expanding abscess and associated edema can lead to ischemia of the pulp space and, ultimately, slough of the tactile portion of the finger pad.

The *clinical presentation* of a felon typically includes a red, swollen, and painful fingertip. There is a history of penetrating trauma in approximately two-thirds of cases (17). Early in the course of the infection, the patient complains of an aching pain that increases when pressure is applied to the fingertip. The pain rapidly becomes severe and throbbing. Systemic signs and symptoms are rare. On examination, the fingertip is extremely tender, and there is erythema and swelling of the distal pulp space. As a rule, the swelling does not extend proximal to the distal interphalangeal joint. Fluctuance is generally present within 48 hours. In some cases, the abscess will point, whereas in others there will be a more diffuse collection of pus. In advanced cases, there may be necrosis of the tactile portion of the finger pad. Other complications of an untreated felon include necrosis of the distal phalanx secondary to osteomyelitis, pyogenic arthritis of the distal interphalangeal joint and, rarely, a flexor tenosynovitis from proximal extension (17).

The *differential diagnosis* of a felon includes cellulitis of the fingertip, a severe run-around infection, and herpetic whitlow. In cellulitis of the fingertip, fluctuance is usually absent, and pain, tenderness, and swelling are less severe. In addition, unlike a felon, cellulitis will often spread proximal to the distal interphalangeal joint. Patients with a severe run-around infection have fluctuance of the eponychium and both lateral nail folds. In contrast, the

fluctuance associated with a felon is much greater in the distal pulp space. Patients with herpetic whitlow usually complain of dysesthesia or a burning sensation of the distal phalanx. Despite associated erythema and swelling, however, the distal pulp space usually remains soft.

The diagnosis of a felon is made clinically following a detailed history and physical examination. Radiographs of the affected digit may be needed in patients with a history of trauma or to assess for the presence of a foreign body or osteomyelitis. Laboratory tests may be helpful in patients with comorbidities (e.g., diabetes) or clinical toxicity but are otherwise unnecessary. Wound cultures may be helpful in immunocompromised patients.

ED management depends upon the extent of infection. If the patient presents in the early stages of the infection, before the onset of fluctuance, management includes immobilization, elevation, warm soaks, and an oral antibiotic effective against *CA-MRSA,* methicillin-sensitive *S. aureus* and *Streptococcus* species (Table 147.1). Surgical drainage is indicated when there is fluctuance present or if associated swelling threatens to interrupt blood flow to the distal pulp space. Although the presence of pus may be difficult to assess in some patients, it is usually present if the process has been going on for more than 48 hours.

The goal of surgical intervention is to provide adequate drainage without creating a disabling scar or unstable fat pad, injuring the digital artery and nerve, or violating the flexor tendon sheath, causing an iatrogenic flexor tenosynovitis. A variety of surgical approaches have been suggested, but many are associated with a high incidence of complications and are no longer recommended. At the present time, the *unilateral longitudinal* approach is the technique most often used (1) (Fig. 147.4).

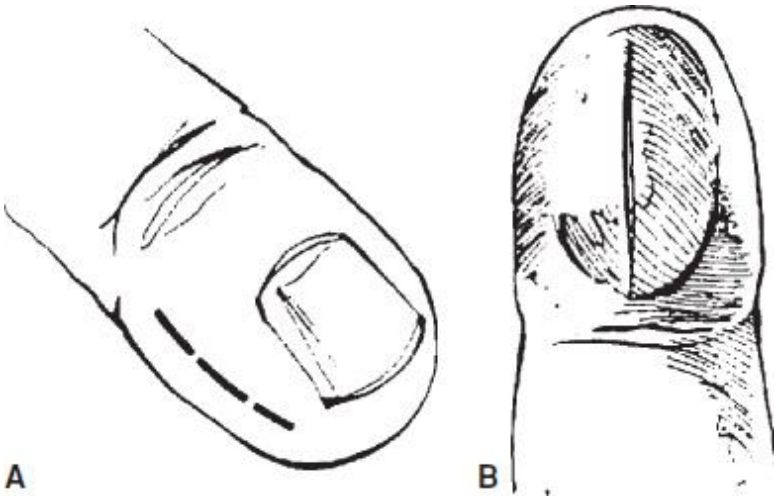

FIGURE 147.4 Incisions for drainage of felons. **A:** Unilateral longitudinal approach. Make the incision dorsal to the neurovascular bundle to prevent permanent sensory loss or ischemia of the distal fat pad. **B:** Midline longitudinal incision (recommended for patients with a draining sinus or pointing abscess on the volar surface of the fingertip). Do not let the incision cross the distal flexion crease as this may result in a disabling scar. (Redrawn from Neviaser RJ. Infections. In: Green DP, ed. *Operative Hand Surgery,* 3rd ed. New York, NY: Churchill Livingstone; 1993:1025.)

After a digital block, place a tourniquet (sterile Penrose drain) around the proximal portion of the digit as described previously. Make a unilateral longitudinal incision dorsal to the neurovascular bundle on the ulnar side of the index, long, and ring fingers and on the radial side of the thumb and little finger. Start the incision approximately 0.5 cm distal to the distal flexion crease and extend it in a straight line to a point in line with the beginning of the hyponychium. Carefully insert the blade deeper and deeper until the abscess is entered and then enlarge the opening of the cavity using a small Kelly clamp until complete evacuation is achieved. Avoid blunt rupture of all the fibrous septa because it may result in an unstable fat pad. Irrigate the cavity with saline and pack the wound with 0.25-in gauze packing. After the procedure, cover the wound with gauze and place the patient in a splint or bulky dressing that protects the finger and limits movement.

For patients with a draining sinus or pointing abscess on the volar surface of the fingertip, a midline longitudinal incision is recommended (Fig. 147.4) (17). Because the abscess cavity lies directly under the draining sinus or area of pointing, a midline longitudinal incision made directly through this area produces excellent drainage with few complications. For these patients, make the incision through the sinus (or over the area of pointing) starting 0.5 cm distal to the distal flexion crease and extend it to the beginning of the hyponychium. Do not let the incision cross the distal flexion crease as this may result in a disabling scar. After drainage and irrigation, pack the wound with 0.25-in gauze and then dress and splint the finger as described previously.

Most patients with a felon may be discharged from the ED. Instruct the patient to keep the affected digit clean and dry and to elevate the hand to reduce pain and swelling and facilitate healing. Prior to discharge, provide prescriptions for an analgesic and an appropriate oral antibiotic (Table 147.1). It is prudent to reevaluate in 48 hours. If the wound is healing well, remove the gauze packing and start warm soaks. Patients who develop pyogenic arthritis, flexor tenosynovitis, osteomyelitis, or an ischemic digit require immediate consultation with a hand surgeon, along with admission for more aggressive management.

Common Pitfalls

- Failing to recognize the need for surgical drainage.
- Improperly placed incisions. A volar incision that crosses the distal flexion crease may cause a disabling scar, whereas a lateral incision not made dorsal to the neurovascular bundle may result in permanent sensory loss or ischemia of the distal fat pad.
- Blunt rupture of all the fibrous septa is not recommended because it may results in an unstable fat pad.

HERPETIC WHITLOW

Herpetic whitlow is a viral infection of the fingertip caused by type 1 and type 2 herpes simplex viruses. This infection is spread by direct

contact with infected individuals. The disease most often affects adults with genital herpes and patients of all ages with herpetic gingivostomatitis (23). It is considered an occupational hazard for individuals who handle oral–tracheal secretions, including dentists, dental hygienists, anesthesiologists, nurses, and other healthcare providers (1). Herpetic whitlow has also been described in patients after human bites (24) and a very aggressive and destructive form of the disease may affect patients with AIDS (25,26). The infection most often affects the distal pulp space and, occasionally, the proximal and lateral nail folds (23). The fingers are affected more often than the thumb. Herpetic whitlow is self-limited and usually resolves in 2 to 3 weeks. Rare complications include systemic viremia, ocular infection, nail dystrophy, nail loss, scarring, and localized hyperesthesia or hypoesthesia (27). About 20% to 50% of patients experience recurrent infections that tend to be less severe than the original (27).

Patients with herpetic whitlow typically describe a prodrome of throbbing pain and dysesthesia or burning sensation of the distal phalanx. This is usually followed by swelling and erythema. Despite associated swelling, however, the distal pulp space usually remains soft. This helps to differentiate herpetic whitlow from a felon, in which there is tense swelling of the distal pulp space. One or more small vesicles then appear and often coalesce to form bullae. Some patients may also have associated fever, lymphadenopathy, lymphangitis, and constitutional symptoms (27).

On examination, tenderness is present but is usually much less severe than that seen with bacterial infections. The vesicles may contain fluid that is clear, turbid, or occasionally hemorrhagic but not purulent. If purulence is present, it suggests the possibility of a secondary bacterial infection. After 10 days, the vesicles or bullae will begin to crust over and, shortly after this, the area peels away to reveal normal skin.

The diagnosis of herpetic whitlow is clinical. If uncertainty exists, the diagnosis can often be confirmed by a Tzanck smear or viral culture. Perform a Tzanck smear by first unroofing a vesicle and scraping the base with a wooden applicator. Spread the scrapings on

a slide and air dry or fix with ethyl alcohol. Finally, stain the slide with Giemsa or Wright stain or with methylene blue and examine for the presence of multinucleated giant cells (27). If the Tzanck smear is negative or cannot be performed, a culture can be obtained. This is more sensitive than a Tzanck smear, but results take up to 48 hours. Additional tests include serum antibody titers and lesion specimen antigen detection (27).

The *ED management* of herpetic whitlow should include immobilization, elevation, and analgesia. Cover the digit with a dry dressing to reduce the spread of infection. The use of acyclovir (200 mg, 3 to 4 times daily) has been shown to prevent or greatly decrease recurrence rates in cases of culture-proven herpetic whitlow (28). It is also indicated for severe infections in immunocompromised patients (28). Topical acyclovir has not been shown to be effective in the treatment of herpetic whitlow. Incision and drainage are contraindicated because it can result in secondary bacterial infection.

Patients with herpetic whitlow may be discharged from the ED with follow-up in 7 to 10 days with their primary care physician or a hand specialist. Discharge instructions should include recommendation to return to the ED for any signs of secondary bacterial infection. If there is a suspicion of an associated bacterial infection on initial presentation, consultation with a hand surgeon is recommended.

Common Pitfalls

- Misdiagnosing herpetic whitlow as a felon or paronychia requiring incision and drainage. Surgical intervention causes unnecessary discomfort and may lead to secondary bacterial infection.

FLEXOR TENOSYNOVITIS

Flexor tenosynovitis is an infection of the digital flexor tendon sheaths of the upper extremity. This infection can be one of the most devastating hand infections encountered in clinical practice. It is most commonly caused by a penetrating injury, particularly at the distal and proximal flexion creases where the tendon sheaths are

more superficial. It may also result from direct extension of a neighboring infection and, rarely, by hematogenous or lymphatic spread. The thumb, index finger, and middle fingers are the digits most commonly involved, and the right hand is affected about twice as often as the left hand. If the disorder is not recognized and treated early, purulence within the tendon sheath can destroy the delicate gliding mechanism. Persistent infection leads to the formation of adhesions, resulting in severe limitation of movement. If allowed to continue, the infection will eventually destroy the blood supply to the tendon, producing tendon necrosis. Risk factors associated with poor outcomes include age greater than 43 years; the presence of diabetes mellitus, peripheral vascular disease, or renal failure; the presence of subcutaneous purulence; digital ischemia; and polymicrobial infections (29).

The *clinical presentation* of flexor tenosynovitis is one of severe pain, swelling, and limited motion of the affected digit. There is a history of penetrating trauma in approximately 90% of cases (30). Kanavel (31) described four cardinal signs of flexor tenosynovitis: (a) tenderness over the course of the tendon sheath, (b) symmetric swelling of the entire digit, (c) a flexed position of the finger at rest, and (d) excruciating pain on passive extension of the finger. The latter is the most valuable of these signs and may be the only one present very early in the disease process (32). It is also important to note that not all of these findings need be present to make the diagnosis; clinicians should have a high level of suspicion if even only one of these signs is present. Moreover, patients with medical comorbidities such as diabetes mellitus or IV drug use or those with compromised immune systems may not exhibit Kanavel signs as dramatically as those with healthy immune systems (30).

In established infections, swelling frequently involves the dorsum of the hand. This is most often due to lymphatic drainage from the affected digit rather than from extension of infection. Dorsal swelling is usually less than that seen with a thenar or midpalmar space infection. If the patient does not seek medical treatment early, the infection may spread to one of the deep palmar spaces, especially the thenar space and midpalmar space, or to adjacent bone or joints,

causing an associated osteomyelitis or septic arthritis, respectively. Infection of the tendon sheath of the little finger or thumb may extend to involve the ulnar bursa and radial bursa, respectively, with resulting pain and tenderness in the palm and wrist. When this occurs, the entire hand becomes swollen, particularly the dorsum (1).

The *differential diagnosis* of flexor tenosynovitis includes a palmar space infection, cellulitis, osteomyelitis, and septic arthritis. However, the diagnosis of flexor tenosynovitis can usually be made if a detailed physical examination is performed, with emphasis on identifying the four cardinal signs of Kanavel. The finding of excruciating pain on passive extension of the digit is particularly helpful because it is often present early in patients with flexor tenosynovitis and is generally not seen with other hand infections.

The *ED evaluation* should include radiographs of the affected digit to look for a foreign body and osteomyelitis. A complete blood cell count and blood cultures may be helpful in those individuals with systemic involvement. Urethral or endocervical cultures for *Neisseria gonorrhoeae* may be helpful in the appropriate clinical setting. Other tests should be guided by the patient's presenting complaints, underlying medical problems, and the need for operative intervention.

The *ED management* of flexor tenosynovitis includes elevation and immobilization of the affected hand, initiation of intravenous antimicrobial therapy, relief of pain, and consultation with a hand surgeon. Initial antimicrobial therapy should be broad-spectrum, aimed at both gram-positive aerobic bacteria (including CA-MRSA) and anaerobic organisms (Table 147.1). Current recommendations in immunocompetent patients include IV vancomycin or IV clindamycin as first-line agents (30). Piperacillin/tazobactam or aztreonam should be added for suspected gram-negative infection (i.e., infection in a diabetic or immunocompromised patient) (30). Patients who present with flexor tenosynovitis secondary to a human bite need coverage for *Eikenella,* which is resistant to clindamycin, cephalexin, metronidazole, and erythromycin. Fortunately, penicillin G, ampicillin, amoxicillin/clavulanate, trimethoprim/sulfamethoxazole and most fluoroquinolones provide acceptable coverage for *Eikenella*

(11). Patients who present with infections following a cat bite have a high incidence of Pasteurella multocida, which is generally sensitive to amoxicillin/clavulanate (this also covers methicillin-sensitive *S. aureus*), cefuroxime axetil, doxycycline, and penicillin G (11). Patients with evidence of disseminated gonorrhea should receive intravenous ceftriaxone.

All patients with suspected flexor tenosynovitis require consultation with a hand surgeon and admission to the hospital. If the patient presents within the first 24 to 48 hours, conservative therapy with continued elevation and immobilization, intravenous antimicrobial agents, and close observation may be attempted. If the patient's condition is not markedly improved within 12 to 24 hours, surgical drainage is indicated (30). The choice of conservative versus operative management should be left to the consulting surgeon.

Common Pitfalls

- Failing to suspect the diagnosis on initial presentation. A careful history and physical examination, with close attention to the cardinal signs of flexor tenosynovitis and a low threshold for consultation, will help avoid a delay in diagnosis.
- Misdiagnosing early flexor tenosynovitis as simple cellulitis.
- Failing to admit a patient with flexor tenosynovitis.

WEB SPACE (COLLAR BUTTON) ABSCESS

A web space abscess usually results from a break in the skin surrounding an infected palmar blister. Consequently, it is seen most often in individuals who do manual labor. Patients present with significant volar infection and dorsal web space swelling. If left untreated, the infection spreads dorsally to the dorsal subcutaneous space and deep into the palmar web space creating an hourglass configuration reminiscent of old collar buttons. As a result, a web space abscess is also known as a *collar button abscess.* Rarely, an untreated infection in the web space between the index and middle fingers will spread medially to involve the other two web spaces.

The *clinical presentation* includes pain and swelling of the involved web space and surrounding palm. Systemic signs and symptoms are unusual in uncomplicated infections. Examination reveals tenderness and swelling of the affected web space. Anteroposterior pressure over the web space elicits severe discomfort. Swelling may be more prominent on either the palmar or the dorsal aspect, depending on the nature of the infection. Because of pus and swelling, the fingers adjacent to the affected web space are held abducted at rest. Untreated infections may spread to involve the tendon sheath or palmar space, or dissect distally along the course of the lumbricals, leading to tissue slough. Rarely, the infection will spread to involve the dorsal subaponeurotic space. If this occurs, patients will have pain, tenderness, and fluctuance involving the dorsum of the hand.

The *differential diagnosis* includes a dorsal subcutaneous space infection, an infected palmar blister, and a deep palmar space infection. As with other infections of the hand, a careful history and physical examination will lead to the correct diagnosis. In a dorsal subcutaneous space infection, the fingers are not held abducted at rest, and palmar tenderness is minimal or absent. Although infection of a palmar blister usually precedes a web space abscess, pain and tenderness are mild in comparison and are localized over the blister, not the web space. Furthermore, swelling is usually minimal and, when present, does not involve the dorsum of the hand. The findings associated with a deep palmar space infection vary with the involved space and are discussed in the next section.

The diagnosis of a web space abscess is made clinically. Radiographs of the affected hand are recommended if a foreign body or osteomyelitis is suspected but are otherwise unnecessary. Laboratory testing may be helpful in those individuals with systemic involvement or significant comorbidities or as needed prior to surgery.

ED management includes elevation of the affected hand, parenteral opiate analgesics, and initiation of antimicrobial therapy, (Table 147.1). Patients with suspected web space infection require consultation with a hand surgeon and admission to the hospital. Definitive management requires drainage in the operating suite.

Common Pitfalls

- Incorrectly diagnosing a primary dorsal space infection because of the presence of dorsal edema.
- Failing to recognize palmar involvement when dorsal edema is more prominent.
- Failing to recognize web space involvement in a patient with an obviously infected palmar blister.
- Failing to request hand surgery consultation.

PALMAR SPACE INFECTIONS

The palm contains four fascial spaces that are important sites of infection: the thenar space, the midpalmar space, the hypothenar space, and Parona's space. These compartments may become infected from direct penetrating trauma, from contiguous infection, such as a tenosynovitis or osteomyelitis or, rarely, from hematogenous seeding. Deep-space infections may be associated with significant morbidity and permanent loss of function; thus, prompt diagnosis and treatment are essential.

The *clinical presentation* of patients with a palmar space infection depends on which space is involved. However, any patient, regardless of the space involved, may present with fever, chills, and other manifestations of a serious infection.

A *thenar space* infection causes severe pain and tenderness and tense swelling of the thenar eminence. Because lymphatic drainage from the palm is directed dorsally, there is usually marked dorsal edema, as well. However, there is little, if any, tenderness over the dorsum of the hand. Fluctuance is often present in the web space between the thumb and index finger. The thumb is held abducted and flexed; passive adduction produces severe pain.

In contrast, patients with a *midpalmar space* infection have pain and tenderness over the central palm. There is marked fluctuance and swelling of the midpalmar space, resulting in a loss of normal palm concavity. In severe infections, there is frequently a bulge or convexity of the palm, a finding considered by Mann (33) to be almost pathognomonic of a midpalmar space infection. As with other

serious hand infections, there is also edema over the dorsum of the hand but no tenderness, erythema, or fluctuance. Motion of the middle and ring fingers is painful and limited.

Infection of the *hypothenar space* is rare. There are pain and fullness over the hypothenar eminence, with a noticeable lack of swelling in the palm and fingers.

Isolated infections in *Parona's space* are also rare; infections here are usually associated with tenosynovitis or other deep space infections that have propagated into the forearm. Patients will have pain with finger flexion and may present with an acute carpal tunnel syndrome (1).

The *differential diagnosis* of a palmar space infection includes a cellulitis or superficial abscess of the palm, a web space infection, and flexor tenosynovitis. Both a cellulitis and a superficial (subcutaneous) abscess of the palm produce pain and tenderness that may not be localized to a particular space. Moreover, unless there is digital involvement, movement of the fingers or thumb causes little, if any, discomfort.

ED evaluation should include radiographs to look for foreign body, osteomyelitis, or gas in the tissues. A complete blood count and blood cultures may be helpful in those individuals with systemic involvement.

The *ED management* of palmar space infection includes elevation and immobilization of the affected hand, parenteral opiate analgesics, and initiation of antimicrobial therapy (Table 147.1). All patients with a suspected palmar space infection require consultation with a hand surgeon and admission to the hospital. Definitive management requires drainage in the operating suite.

Common Pitfalls

- Failing to appreciate the presence of a serious palmar space infection.
- Misinterpreting the presence of dorsal edema as a dorsal cellulitis.
- Failing to request hand surgery consultation.

CHAPTER 148

Low Back Pain

David Della-Giustina

Low back pain is a common complaint that affects up to 90% of the population at some point in their lives. Approximately 7.6% of all US adults report at least one episode of severe acute low back pain within a 1-year period (1). Up to 85% of patients with low back pain will have no definite etiology determined for their symptoms (1,2). Fortunately, despite the lack of a definite etiology, almost 85% to 90% of patients will have resolution of their symptoms within 1 month (1,3). In approaching the patient with back pain, patients may be categorized into four groups: (a) nonspecific back pain, (b) back pain with radiculopathy, (c) back pain associated with another specific spinal cause, and (d) back pain in children (1). By far, the majority of patients with back pain presenting to the emergency department (ED) fall into the first category.

CLINICAL PRESENTATION

The clinical presentation of the patient with back pain ranges from the patient with mild pain who requires a work excuse to the patient with the severe, unrelenting pain of an epidural abscess. It is more important that one provides a thorough evaluation of each patient, focusing on the red flags found in the history and physical examination that raise suspicion for serious disease, rather than recognizing a particular classic presentation for the various diseases (Table 148.1).

TABLE 148.1
Red Flags in the History and Physical Examination

History
Pain longer than 6 wk
Age <18 or >50 yr
History of trauma
Radicular pain below the knee
Neurologic complaints (paresthesias, anesthesia, weakness)
Incontinence of bowel or bladder
Night pain
Unrelenting pain despite rest and analgesics
Fever, chills, and night sweats
History of injection drug use
History of cancer
Physical Examination
Fever
Patient writhing in pain
Point vertebral tenderness
Neurologic deficits
Positive straight leg raise

Sciatica is a broad term that is defined as a radicular pain into the leg in the distribution of a lumbosacral nerve root (see back cover), which is often accompanied by a neurosensory or motor deficit (1,4). Back pain with radiculopathy, which is a better description than sciatica, only affects 1% of patients with low back pain (4). Although there are many etiologies for back pain with radiculopathy, it most commonly occurs as a result of a herniated disc. Generally, these patients have a more protracted course than nonspecific back pain patients, with only 50% of patients with sciatica recovering within 1 month. However, of all back pain patients with radiculopathy, only 5% to 10% will require surgery (1,2,4).

Children are in a separate category, because back pain is an unusual condition in children and is much more likely to be pathologic rather than nonspecific. The differential diagnosis for the child with back pain is different from that of the adult, and it varies further based on the age of the child. Because of the higher potential for serious disease, one should approach the child with back pain more aggressively.

DIFFERENTIAL DIAGNOSIS

Adults with Nonspecific Back Pain

The majority of patients seen in the ED for acute low back pain have symptoms that fall into the category of nonspecific back pain (Fig. 148.1). This syndrome is known by many other names such as idiopathic back pain, mechanical back pain, back sprain/strain and lumbago. Essentially, it is an episode of acute low back pain without associated radiculopathy or neurologic deficits.

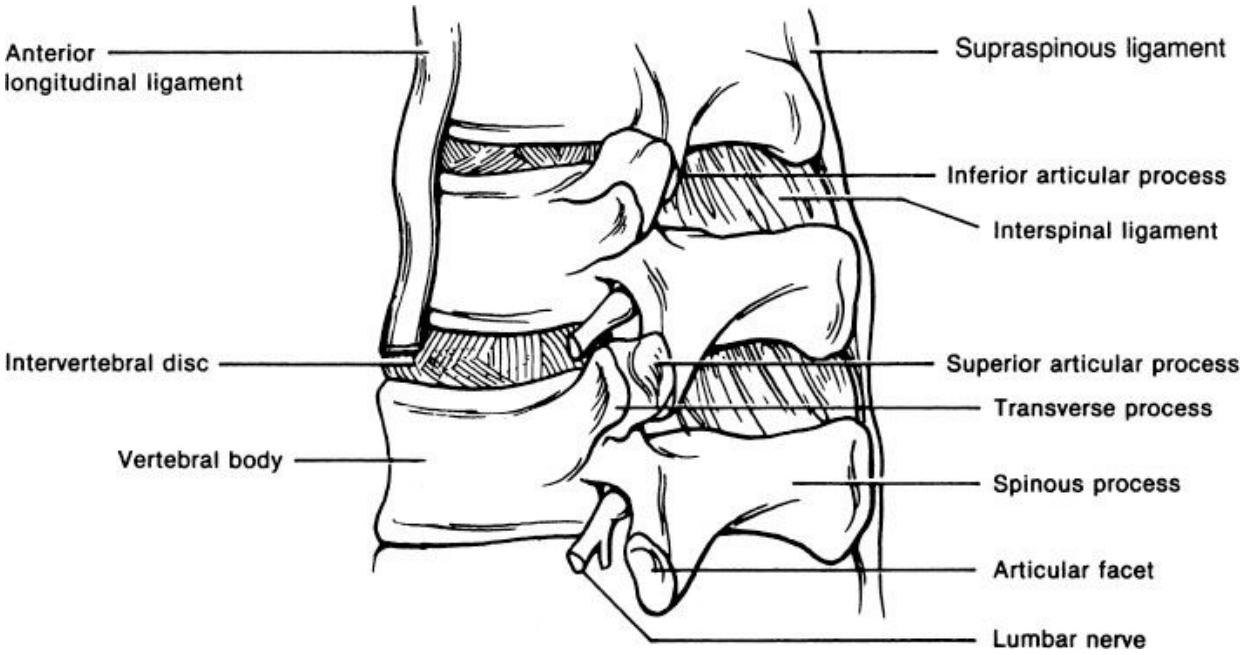

FIGURE 148.1 Normal anatomy of the lumbar spine.

The patient typically complains of mild-to-moderate pain in the lumbar area, which may radiate to the buttocks or thigh, is worsened by activity and is relieved with rest. The inciting incident is usually unremarkable, varying from an unusual posture for a period of time to lifting a heavy object. Physical examination typically reveals mild paraspinal tenderness, negative straight leg raise testing, normal neurologic examination, and no other significant findings. The investigation of red flags, if any, from the history and physical examination is negative. Because 85% to 90% of these patients will have a spontaneous resolution of their symptoms within 4 weeks,

there is no need to perform diagnostic testing unless red flags are uncovered. This saves the patient unnecessary pain, expense and radiation exposure.

Spinal Infection

Vertebral osteomyelitis and spinal epidural abscess are uncommon etiologies for back pain. However, because of the potential morbidity and mortality that result from missed infection and due to the fact that the incidence of these infections is increasing, one must remain vigilant concerning these possibilities (5,6). These infections occur more commonly in injection drug users, the immunocompromised, diabetics, elderly, those who have an ongoing or recent infection and those who have had spinal surgery (5,6). These infections frequently occur secondary to hematogenous spread of *Staphylococcus aureus.* Patients with spinal infection typically present with moderate-to-severe back pain accompanied by fever, chills, unrelenting pain, night sweats, and weight loss. With epidural abscess, the patient may have associated radicular pain and neurologic symptoms. Some patients with epidural abscess may present with sepsis. However, one cannot rely on the presence of a fever, unrelenting pain or neurologic deficit to rule in this disease (5,6). In evaluating patients for suspected spinal infection, the peripheral white blood cell (WBC) count may be elevated or normal, but the erythrocyte sedimentation rate (ESR) and C-reactive protein are almost always elevated with the one caveat that the more severely immunocompromised may not demonstrate this elevation (5–7). One should always consider back pain, especially thoracic back pain, in a patient who is an injection drug user as a spinal infection until proven otherwise.

Radiculopathy

Back pain with radiculopathy is a set of symptoms caused by compression or irritation of the lumbosacral nerve roots that form the sciatic nerve (L4 to L5, S1 to S3). Symptoms include unilateral pain in the back, buttocks, posterior leg, and foot, as well as tingling and weakness. The differential diagnosis includes any cause of

compression or inflammation of the spinal nerve roots, cauda equina, and spinal cord. The major cause of sciatica is herniated disc. However, in the ED, one should consider other etiologies, including spinal stenosis and compression of the cauda equina or spinal cord by tumor, infection, or hematoma.

Herniated Disc

Although radiculopathy is seen in only 1% of patients with low back pain, it is a common presentation of a symptomatic herniated disc. Ninety-five percent of herniated discs involve either the L4 to 5 or L5 to S1 intervertebral discs (1,2,4). Herniated disc most commonly occurs in patients during their fourth or fifth decades of life. Patients often complain of weeks of nonradicular low back pain preceding the onset of the radicular symptoms. The radicular symptoms are the hallmark of the nerve root compression and usually become the prominent symptom, with a diminution of the back pain. Clinically, the diagnosis of herniated disc is made by localizing the pain to an isolated nerve root and demonstrating neurologic dysfunction in the distribution of that nerve root (see back cover). If a diagnosis of herniated disc is entertained, one should ensure that only one nerve root is involved. The involvement of multiple nerve roots is cause for concern for a larger central disc herniation or a spinal mass.

Epidural Compression Syndrome

Epidural compression syndrome is a collective term encompassing spinal cord compression, cauda equina syndrome, and conus medullaris syndrome. This term is commonly used to group these syndromes together for two reasons. First, the presentation for these syndromes is similar, except for the level of the neurologic deficit. Secondly, the initial evaluation and management of these syndromes is similar, until the actual diagnosis is known. This syndrome may be caused by compression of the cauda equina or spinal cord by tumor, large central disc herniation, infection, or hematoma. The patient usually presents with minimal-to- moderate back pain with bilateral neurologic deficits and incontinence. The most common sensory

deficit found in cauda equina syndrome occurs over the buttocks, perineum, and posterior-superior thighs in the "saddle" distribution (8). Urinary retention is the most consistent finding in cauda equina syndrome (sensitivity 90%) (1,8). This finding proves useful in evaluating the patient with a benign history and physical examination but who complains of urinary incontinence. By evaluating a postvoid residual, a negative test (no urinary retention) makes it extremely unlikely that the patient has incontinence because of epidural compression. All patients with suspected epidural compression require emergent magnetic resonance imaging (MRI) imaging and neurosurgery consultation.

Spinal Stenosis

Spinal stenosis is a narrowing of the spinal canal that may occur at single or multiple levels and is associated with radiculopathy or claudication (9,10). Generally, spinal stenosis is a cause of chronic back pain, but it has associated flares of acute pain. The symptoms, which usually begin in the sixth decade, include low back pain that is aggravated by prolonged standing and spinal extension and relieved by rest and forward flexion. The classic symptom for spinal stenosis is pseudoclaudication, although this is seen in only 60% of patients. Pseudoclaudication is pain of the lateral legs that occurs with walking and is relieved with rest. This pain is termed *pseudoclaudication* because it is caused by neurologic compression associated with the upright position rather than muscle ischemia because of arterial insufficiency. The more appropriate term for this symptom now is neurogenic claudication (9,10).

Back Pain in Children

Children rarely present to the ED with complaints of back pain. When they do, one must perform a more thorough diagnostic evaluation, as there is a much higher probability of a serious treatable disorder. If the pain is associated with a recent increase in physical activity or involvement in sports such as football, dance and gymnastics, then one should consider spondylolysis or

spondylolisthesis as the cause of the pain. Other etiologies to consider in the child younger than age 10 are discitis, tumor, and osteomyelitis. Etiologies for children age 10 years and older include spondylolysis, spondylolisthesis, Scheuermann disease, tumor, vertebral osteomyelitis, herniated disc, and ankylosing spondylitis.

ED EVALUATION

The ED evaluation must concentrate on the identification of red flags in the history and physical examination (Table 148.1). The presence of red flags should alert the clinician that serious pathology might be present and a more aggressive diagnostic evaluation is indicated. The absence of red flags means that it is unlikely that the patient has significant disease, and no diagnostic tests are required. Therefore, the majority of patients with back pain encountered in the ED require no diagnostic testing.

Children without an obvious etiology for their back pain should be evaluated with a complete blood count (CBC), ESR, urinalysis (UA), and plain spinal radiography.

History

Back pain may be divided into three categories based on the duration of the symptoms: acute (<6 weeks), subacute (between 6 and 12 weeks), and chronic (>12 weeks). Pain that is subacute or chronic is a red flag because 85% to 90% of back pain episodes resolve within 4 to 6 weeks. Patients with persistent back pain for more than 6 weeks require further diagnostic evaluation.

Patients older than 50 years or younger than 18 years raise a red flag because of the higher probability of significant pathology, such as tumor or infection. Those patients younger than age 18 years have a higher likelihood of congenital and bony abnormalities, such as spondylolysis and spondylolisthesis. In patients older than age 50 years, causes such as neoplasia, fracture, or referred pain from vascular disease, pancreatitis, and other intra-abdominal or retroperitoneal processes are more common.

A history of trauma suggests fracture and is usually a readily available historical clue. In an otherwise healthy patient, a major mechanism (motor vehicle crash or a fall from a significant height) is required to cause vertebral fracture. However, one must consider that the patient with osteoporosis may sustain a vertebral fracture from even minimal trauma.

A history of radicular pain suggests nerve root compression. Patients with radiculopathy commonly complain more of the leg symptoms than the back pain. In addition to the radicular symptoms, one must inquire about neurologic deficits such as weakness, paresthesias, anesthesia, gait disturbances, and bowel and bladder incontinence. Any neurologic deficit raises a red flag for compression of at least a single spinal nerve root but may signal compression of the cauda equina or spinal cord. Bilateral or rapidly progressive symptoms or urinary or fecal incontinence are especially worrisome and suggest epidural compression.

The typical description for a benign etiology of back pain is that of a dull, aching pain, which usually worsens with movement but improves with rest. Atypical pain features, such as night pain or unrelenting pain despite rest raise red flags for infection and tumor. Features suggestive of disc herniation include pain that is worsened with prolonged sitting, sneezing, coughing, or the performance of the Valsalva maneuver (2,11). Finally, bilateral sciatica pain that worsens with activities such as prolonged standing, walking, and back extension and is relieved by rest and forward flexion is consistent with spinal stenosis (9,10).

Constitutional symptoms such as fever, chills, night sweats, malaise and an undesired weight loss are red flags that suggest infection or malignancy. The significance of these symptoms is increased if the patient has additional infectious risk factors such as injection drug use, immunocompromise, recent or ongoing bacterial infection, or a recent genitourinary or gastrointestinal procedure.

A history of cancer raises suspicion for spinal metastases. Back pain is the initial symptom of spinal metastases in 83% to 96% of these cases (1,12). Malignancies at a high risk to metastasize to the

spine include breast, lung, thyroid, kidney, prostate, myeloma, lymphoma, and sarcoma.

Physical Examination

The physical examination is directed toward verifying neurologic complaints, identifying neurologic deficits and uncovering red flags (Table 148.1). The presence of fever raises a concern for spinal infection. However, the presence of fever is insensitive, ranging from 27% for tuberculosis osteomyelitis to 50% for pyogenic osteomyelitis and 83% for spinal epidural abscess (8). Patients with pyelonephritis may also present with fever and back pain, though the more dangerous spinal epidural abscess must first be excluded, particularly in the injection drug user or immunocompromised patient. All patients with back pain require an abdominal examination to evaluate for bruits, masses, tenderness, or an enlarged and pulsatile aorta consistent with an aortic aneurysm. Many abdominal disorders present with referred back pain.

In children, one should specifically evaluate for the presence of birthmarks, such as café au lait spots (indicative of neurofibromatosis), as well as midline skin abnormalities of the back that may indicate underlying developmental spinal abnormalities.

Examination of the back should include a search for evidence of underlying infection or trauma. Inspect the back, looking for contusion or swelling consistent with trauma and erythema, warmth or drainage consistent with infection. Point tenderness to percussion of the vertebral bodies is found with bacterial infection with a sensitivity of 86%, but is nonspecific (8). Straight leg raise testing is performed to evaluate for evidence of a herniated disc with nerve root compression. A positive test produces a radicular pain that radiates below the knee. Reproduction of the patient's back pain is not a positive test (1,2,8). A positive straight leg raise test is 80% sensitive for a L4–5 or L5–S1 herniated disc. Radicular pain in the affected leg when elevating the asymptomatic leg (positive crossed straight leg raise test) is highly specific, though insensitive, for nerve root compression by a herniated disc (1,2,8).

The neurologic examination is the most important part of the physical examination. The examination should evaluate lower extremity strength, sensation, and reflexes (see back cover). Rectal examination does not need to be performed on all patients with back pain; however, it should be performed on those patients with red flags or neurologic findings.

Laboratory Testing

If the patient has red flags for infection or tumor, one should obtain a CBC, UA, and an ESR. With infection, the WBC count may be normal or elevated, but the ESR is usually elevated although it is nonspecific. C-reactive protein (CRP) is another nonspecific marker of inflammation and may be elevated like the ESR, though its utility in this setting is not clear. The UA can be positive in infection, if it is the source of hematogenous spread, but it is usually normal.

Imaging Studies

Plain spinal radiographs should always be obtained in children or in adults when there is concern of fracture, and should be considered as an initial imaging study for those with suspected spinal infection, tumor, or neurologic dysfunction. In adults, only anteroposterior (AP) and lateral views of the lumbar spine are necessary. Oblique views and a cone-down view of L5–S1 add minimal information and more than double the radiation exposure (4). In children, the oblique views should be obtained after reviewing the AP and lateral views because these additional views may demonstrate spondylolysis or spondylolisthesis, which are common problems in children. It is not necessary, however, to obtain plain radiographs in the majority of patients, who have nonspecific back pain or suspected disc herniation.

MRI is the imaging study of choice for patients with suspected epidural compression syndrome, spinal infection, spinal metastases, herniated disc, and spinal hematoma (13). MRI provides the best resolution of the spinal cord, spinal canal, and disc disease. In cases of suspected epidural compression due to tumor, infection or

hematoma, the entire spine should be imaged for two reasons. First, there is a risk of false localization to a spinal level on physical examination. Second, in metastatic spinal cord compression, there is a 10% risk of asymptomatic metastases distant from the affected site that may alter the treatment regimen. Although MRI is the gold standard for disc herniation, it is not necessary to order an emergent study from the ED in the absence of signs or symptoms of epidural compression. For suspected herniated disc, an outpatient MRI is appropriate for those who fail to respond to 4 to 6 weeks of conservative management.

Computed tomography (CT) scanning is superior to MRI in evaluating the bony architecture of the spine, especially in the assessment of a vertebral fracture. However, CT is inadequate for imaging the spinal cord and the spinal canal surrounding the spinal cord. When used in conjunction with myelography (CT-myelogram), CT scanning approaches the accuracy of MRI and should be considered the imaging method of choice in the patient who is unable to undergo an MRI.

KEY TESTING

- CBC and ESR for suspected tumor or spinal infection
- Plain films or CT for suspected fracture
- MRI for suspected epidural compression, spinal infection, or metastases

ED MANAGEMENT

The treatment of patients with nonspecific low back pain should focus on the areas of activity modification, analgesia, and other modalities. In terms of activity modification, patients should continue their routine daily activities as tolerated, using pain as the limiting factor. Routine activity has been demonstrated to allow more rapid recovery than either bed rest or back mobilizing exercise (1,14).

Appropriate analgesia is paramount in treating the patient with nonspecific back pain. The primary treatment regimen should

involve acetaminophen alone or in combination with a nonsteroidal anti-inflammatory drug (NSAID). When employing NSAIDs, one must consider that no single NSAID has been shown as being most effective (1,2,15–17). Thus, one should initiate therapy with a less expensive agent such as ibuprofen, naproxen, or indomethacin. The use of the injectable NSAID ketorolac should be reserved for the patient who is unable to tolerate an oral NSAID. Additionally, NSAIDs should be used with caution in patients at risk of adverse effects, such as the elderly and those with peptic ulcer disease or renal disease.

Muscle relaxants, such as cyclobenzaprine (Flexeril), are often efficacious in treating nonspecific back pain, but clinical trials have not clearly identified which patients benefit from them. Side effects, especially sedation, are common (1,2,15–17). There is no good evidence that the addition of a muscle relaxant to a NSAID provides any additional benefit over NSAIDs alone (17).

Opioid analgesics should also be prescribed for patients with moderate-to-severe back pain. The prescriptions for these medications are best limited to 1 to 2 weeks' duration because of the risk of sedation, addiction, and constipation. Patients should be warned not to use acetaminophen when they are treated with an acetaminophen–opiate combination. There is no proven benefit to the use of oral steroids in the treatment of the patient with acute low back pain (1,16,18).

Manipulation is a controversial area of treatment. Although safe and recommended as effective by the 1995 Agency for Health Care Policy and Research (AHCPR) guidelines, more recent literature shows it is no more effective than exercises and only minimally more effective in improving patient satisfaction with care than giving the patient an instructional booklet (1,3,19,20). Other physical modalities, such as traction, transcutaneous electrical nerve stimulation (TENS) units, diathermy, and ultrasound, appear to be ineffective (1,3).

The treatment regimen for herniated disc mirrors that for nonspecific low back pain, including the use of routine activity as

opposed to bed rest (17), with the exception that manipulation should be used with extreme caution.

The patient with suspected epidural compression requires emergent advanced imaging, specialty consultation, and should be considered for treatment with dexamethasone. The acute use of steroids in the patient with epidural compression from disc herniation and epidural abscess is controversial and there is no definitive answer. For the patient with potentially metastatic disease, a wide range of dosing for dexamethasone (10 to 100 mg IV) has been suggested (21–23). The current recommended approach is to administer 10 to 16 mg of dexamethasone IV to the patient with known cancer and signs of epidural compression (12,21). One should not delay steroid administration while awaiting definitive confirmation by imaging studies. For patients with spinal cord compression due to neoplasm, emergent radiation therapy is also recommended.

In the patient with suspected spinal infection obtain at least two sets of blood cultures, as these are frequently positive. One should discuss the need for antibiotics in the ED with the consultant prior to administration, because these patients may require open or needle guided biopsy with culture of the site. The administration of antibiotics may obscure the culture results. However, patients with paralysis or sepsis because of infection require antibiotics and one should not delay their administration. Empiric antibiotic therapy should be directed against methicillin-resistant *S. aureus* (MRSA), such as parenteral vancomycin, in addition to a third- or fourth-generation cephalosporin due to the potential of a gram-negative bacilli infection (5).

CRITICAL INTERVENTIONS

- Administer dexamethasone in suspected epidural compression due to tumor.
- Administer antibiotics that cover MRSA and gram-negative bacilli in patients with suspected spinal infection.

DISPOSITION

Patients with nonspecific low back pain and back pain with radiculopathy can be discharged home with primary care physician follow-up in 2 to 4 weeks. They should be treated with acetaminophen and NSAIDs, unless contraindicated. Most patients may benefit from a short course (1 to 2 weeks) of opiate analgesia, such as hydrocodone or oxycodone. If patients have a deficit in a single nerve root consistent with a herniated disc, the primary care physician should see the patient within 7 to 10 days. All patients suspected of having an epidural compression syndrome require emergent MRI and consultation in the ED by a spine surgeon. If known or suspected metastatic disease is present, an oncologist should also be consulted. All patients with suspected spinal infection require emergent MRI.

Transfer to another facility is necessary in the patient with suspected spinal infection or epidural compression syndrome, if the facility evaluating the patient is unable to obtain an appropriate imaging study (MRI or CT myelogram) or lacks the appropriate specialists. In patients with suspected epidural compression syndrome due to tumor, steroids should be administered before the transfer.

Common Pitfalls

- Failure to consider a ruptured abdominal aortic aneurysm in the patient older than age 55 years with acute low back pain.
- Overutilization of diagnostic tests in the patient with low back pain and no “red flags.”
- Underutilization of testing in children with back pain, who have a much higher incidence of serious etiologies than adults.
- Failure to consider spinal infection in the immunocompromised patient or the injection drug user with back pain, especially when fever is present.
- Overutilization of MRI in patients with suspected herniated disc. Such patients do not require imaging with MRI unless they fail to improve within 4 to 6 weeks, and it is not required in the ED.

- Failure to administer dexamethasone and order emergent imaging and consultation in patients with suspected epidural compression syndrome.

CHAPTER 149

Foot Disorders

Valerie Dobiesz and Carissa Tyo

Foot pain is a common complaint in the emergency department (ED), and foot disorders can be extremely debilitating. Foot injuries rank second only to knee injuries as the most common injuries associated with sports. Nontraumatic causes of foot pain are usually chronic or subacute in nature. In the vast majority of cases, overuse conditions or improperly fitting shoes are the causes. The emergency physician can often provide symptomatic relief and definitive care. Special attention needs to be given to diabetic patients with foot disorders, as they are at high risk for serious complications.

The vast majority of foot disorders can be diagnosed easily without further testing and can be successfully treated on an outpatient basis. Patients should be referred to a primary care physician, a podiatrist, or an orthopedic surgeon for definitive care and follow-up.

TINEA PEDIS

Tinea pedis is a dermatophyte infection of the soles of the feet, the interdigital spaces, and is often accompanied by onychomycosis (tinea unguium). Superficial mycotic infections are present in 20% to 25% of the world's population and the most common fungal infections of the skin are on the feet (1). Males are more commonly affected, and the incidence increases with age. Occlusive footwear, because it causes moisture and warmth between the toes, and hyperhidrosis predispose to this condition; communal activities such

as swimming and bathing promote its spread. The infection can be acute or chronic and both types are contagious, typically caused by the shedding of skin scales containing hyphal elements. The most frequent dermatophyte involved is *Trichophyton rubrum* (1).

There are four types of tinea pedis. The interdigital type involves maceration and desquamation in the lateral toe spaces, the vesicular type manifests as episodes of unilateral acute vesiculation on the soles, the chronic hyperkeratotic or moccasin type causes dry pruritic erythema with diffuse scaling over the soles, and the ulcerative type presents with vesiculopustular lesions and secondary bacterial infection. Symptoms include extreme itching, burning, and irritation on the soles of the foot and between the toes.

ED management includes a variety of topical antimycotic agents, such as imidazoles, pyridines, allylamines, and benzylamines. These agents should be used twice daily for 1 to 6 weeks depending on the agent used. Widespread infections, cases involving the nails (onychomycosis), cases in patients with immunocompromised states or diabetes, or failed topical therapy are treated with systemic antimycotics such as itraconazole, terbinafine, fluconazole, or the imidazoles. Care should be exercised to observe for signs of opportunistic bacterial superinfection through the disrupted dermal barrier.

PARONYCHIA

Paronychia are soft tissue infections arising along the perionychium and may be acute or chronic in nature. They tend to follow the course of the nail margin and on occasion extend under the nail bed itself. These infections tend to arise acutely after local trauma including nail cutting, hangnail, and nail-biting, though obviously less common on the foot. Small breaks in the skin allow for the entrance of the infecting organism. Symptoms start with local erythema, pain, and swelling. This may then progress to suppurative infection with local abscess formation and, in severe cases, cellulitis and eventually osteomyelitis. In acute infections, the organism is typically *Staphylococcus aureus* and less commonly *Streptococcus* or

Pseudomonas species. In diabetic patients, the infection may be due to mixed flora. Chronic infections due to *Candida* often arise from chronic exposure of the feet to moisture.

ED management options are described in detail in Chapter 147.

PLANTAR WARTS (VERRUCA VULGARIS)

Plantar warts are hyperkeratotic lesions on the plantar surface of the foot caused by the human papillomavirus (HPV) through direct skin contact and are generally self-limited. Each subtype of HPV shows a preference for certain areas of the body, with subtypes 1, 2, 4, 27, and 57 most commonly associated with plantar warts (2,3). They tend to grow endophytically (into the deeper layers of skin) on pressure areas of the feet such as bony prominences or the heel or ball of the foot and may be painful when the patient puts weight on them. Children, especially teens, are more susceptible to infection than adults. Warts are firm and flat with well-defined boundaries and may be brown or gray, with the center containing one or more pinpoints of black representing thrombosed capillaries. Callus formation over the wart is common. Distinguishing warts from calluses may be difficult. Warts occur at any site, whereas calluses appear only on pressure areas. Pinching around the lesion and producing pain supports an underlying wart. If the hyperkeratotic area is scraped, the underlying wart typically bleeds and has a spotted appearance, representing thrombosed vessels.

ED management consists of application of pressure-relieving dressing and administration of analgesics, topical keratolytic agents solutions such as salicylic acid, cantharidin, or dichloroacetic acid, or duct tape occlusion therapy for a maximum of 2 months (4–6). Refractory warts may require cryotherapy with liquid nitrogen, laser, or surgical excision. HPV vaccine may have a role in the treatment of recalcitrant warts (7).

SUBUNGUAL HEMATOMA

Painful and black toenails are often a result of acute trauma or repeated minor trauma from improper footwear, resulting from the

toenails' rubbing on the undersurface of the shoe or the foot sliding forward to jam the toes. If the symptoms are acute, the treatment is drainage of the hematoma with nail trephination, which can be done using a heated paper clip, an 18-gauge needle, or an electrocautery device. To prevent recurrence, the patient can be instructed to use a metatarsal pad under the metatarsal heads or a tongue pad underneath the tongue of the shoe, and instructed to wear shoes with an adequate toe-box.

ONYCHOCRYPTOSIS (INGROWN TOENAIL)

Ingrown toenails are often the result of poorly fitting shoes, abnormal nail growth, or poor nail cutting. A sharp edge of the nail pierces the epidermis of the sulcus and penetrates the dermal tissues. The hallux or great toe of male adolescents is most often involved. Symptoms include pain, swelling, erythema, and purulent drainage of the affected toe. Patients may develop granulation tissue along the nail margin owing to chronic inflammation. Warm soaks are helpful in mild cases, whereas partial resection of the nail (generally a narrow longitudinal strip) may be needed for more severe cases. In the presence of infection, the ED management options are those described for a paronychia (Chapter 147). More definitive treatment should be carried out by a podiatrist or surgeon.

BLISTERS, CALLUSES, AND CORNS

Excessive localized pressure or friction between the foot and improperly fitted shoes or from constant sliding of the foot inside a shoe can result in blisters, calluses, and corns. *Blisters* result from shearing forces, causing fluid to accumulate within the layers of the skin. In one study of endurance sports, blisters were the most common reason for medical attention, accounting for 53% of medical encounters during an adventure race (8). The treatment of blisters is geared toward prevention, with local treatment of hotspots using padding and lubrication to prevent friction over the affected areas. Comfortable, well-fitting shoes and thick padded

socks may help to prevent blister formation and should be considered high priority for management. Once formed, the treatment of blisters is controversial and depends on the needs of the patient. In sports, the patient often desires a rapid return to activity, which may be facilitated by drainage and bandaging of the sites. This drainage may be done with a sterile sharp tool such as a scalpel or needle. The overlying skin should be left intact and a dressing applied. As an open wound, the area should be monitored closely for signs of infection. Infected blisters must be debrided, and antibiotics may be indicated if signs of local cellulitis are present. If the patient does not need to reenter activity, blisters may be left intact and observed for signs of infection.

Calluses develop from excessive pressure, causing hypertrophy of the squamous cell layer of the epidermis on skin that is normally thick, such as the sole. A callus is painless and may be diffuse or localized. Treatment includes regular debridement with a callus file, pumice stone, or scalpel.

A *corn* (Helomata or clavi) is a painful conical thickening of skin with recurrent pressure; the apex of the cone points inward and causes pain. Corns usually occur over bony prominences such as the fourth or fifth toe. When they occur in moist areas, such as between the toes, they are called *soft corns.* Treatment is aimed at prevention with appropriate footwear and padding proximal to the lesions to relieve pressure. These lesions should be aggressively pursued and treated in diabetic patients because of the risk of infection and long-term sequelae.

PIEZOGENIC PEDAL PAPULES

First described in 1968, piezogenic pedal papules are small (2 to 5 mm), white to yellow, and located along the medial or posterolateral aspect of the heel. They tend to be bilateral and are associated with weight bearing. Thought to arise from local pressure, these papules form in long-distance runners with a predisposition to women and children. They arise from a herniation of subcutaneous fat through the collagen matrix of the reticular

dermis of the foot. They may be either symptomatic or asymptomatic and may improve or resolve with elevation of the feet (9). Although no satisfactory medical or surgical treatment exists, heel cups may provide some relief.

BROMHIDROSIS

Malodor of the feet is caused by keratin decomposition in the presence of hyperhidrosis or excessive production of sweat. A corynebacterial overgrowth or fungal colonization may occur, worsening the condition. Treatment includes measures to reduce sweat production and to control secondary infection. Use of talcum powder, spray deodorants, and absorbent insoles may be helpful.

METATARSAL STRESS FRACTURES

Stress fractures are the result of repetitive loading forces, causing the bone to fatigue and eventually fracture. Metatarsal bones are a common site of stress fracture. The most common metatarsal stress fracture occurs at the neck of the second metatarsal and is commonly described in military recruits (march fracture). It is more common in patients with Morton syndrome (the first ray shorter than the second) (10).

Symptoms include localized pain that is worsened by activity or weight bearing and is relieved with rest. Plain x-rays typically do not reveal stress fractures until 10 to 14 days after they occur. Bone scan or magnetic resonance imaging (MRI) may be diagnostic but are not practical or necessary in the ED setting. The condition is treated conservatively by having the patient avoid weight bearing on the site for 4 to 6 weeks, applying ice, and administering nonsteroidal anti-inflammatory drugs (NSAIDs).

BUNIONS (HALLUX VALGUS)

Bunions are inflammation at the first metatarsophalangeal (MTP) joint. Inflammation at the base of the little toe is called a *bunionette* (tailor's bunion). This condition is more common in females in a 10:1 ratio. The hallux valgus deformity consists of lateral deviation

of the hallux and medial deviation of the first metatarsal. The etiology of both is unclear, but hereditary biomechanical abnormalities and improperly fitting shoes may be factors. Symptoms of bunions are pain and erythema at the MTP joint. ED management is focused on analgesia with NSAIDs, bunion pads, ice, and patient education on proper shoes with a wide toe box and no high heels. In severe cases, surgical correction is indicated.

TOE DEFORMITIES (MALLET/HAMMER/CLAW TOES)

Mallet toes are flexion contractures of the distal interphalangeal joint, most commonly of the second digit. Although the exact etiology is uncertain, ill-fitting shoes are believed to contribute. Mallet toes are more common in diabetic patients and may lead to the formation of calluses and corns of the abnormally flexed toe, leading to a risk of infection owing to friction and ultimately ulceration at the pressure points.

Like mallet toes, hammertoes arise from an abnormal flexion contracture in the toe. However, this deformity arises in the proximal interphalangeal joint. Ill-fitting shoes are also believed to contribute to this deformity, with similar attendant problems arising from pressure points along the deformed toes.

Claw toes are also deformities of the toes but tend to arise because of neuromuscular diseases and affect all minor toes equally often. They tend to be associated with extension of the MTP joint and occasionally with flexion of the distal interphalangeal joint. As with mallet and hammertoes, complications arise from abnormal distribution of pressures on the feet.

Treatment of toe deformities starts with local padding and support, with use of well-fitting shoes. Surgical correction may be indicated in some case. Diabetics, in particular, should be referred for podiatric or orthopedic consultation.

CALCANEAL STRESS FRACTURES

Repetitive stress on the calcaneus may over time result in a stress fracture. Patients typically present with insidious onset of heel pain

aggravated by weight-bearing activities. On examination, there is localized tenderness over the medial or lateral aspects of the calcaneus, and pain is elicited by squeezing the calcaneus from both sides, the heel "squeeze" test. It may initially be confused with plantar fasciitis. Radiographs are typically normal initially or show a typical sclerotic appearance on the lateral view parallel with the posterior margin of the calcaneus. Treatment is conservative with rest, administration of NSAIDs, and advising the patient not to put weight on the site.

TARSAL TUNNEL SYNDROME

Tarsal tunnel syndrome (TTS) is a compressive neuropathy of the posterior tibial nerve arising from constriction as the nerve passes through the tarsal tunnel. Symptoms include burning and paresthesias to the heel which may radiate down to the toes or shoot back up the leg. Similar to carpal tunnel syndrome, the condition arises from the increased pressure within the tarsal tunnel contributing to neuropathic dysfunction of the posterior tibial nerve. In addition to paresthesias and pain, the patient may also have numbness, hot/cold sensations, or electric shock sensations down the foot.

The causes of TTS are varied and may arise from pathology in any of the components and contents of the tarsal tunnel. Approximately 50% of the time, the etiology is idiopathic. For the other 50%, a cause may be discernible (11). Bone spurs, ganglion cysts, varicose veins, local inflammation, or acute bony injury are a few examples of potential causes. Treatment depends largely on the etiology of the compression and may include steroid injection, immobilization, and ultimately surgical decompression.

Diagnosis can be made by performing at Tinel sign over the tarsal tunnel. The physician taps over the region just posterior and inferior to the medial malleolus to assess for worsening paresthesia to the foot. Imaging may be useful to assess for potential etiologies. X-rays may elucidate fractures or bone spurs, ultrasound may clarify vascular malformations or varicosities, MRI can demonstrate local

inflammatory problems as well as cystic or mass lesions. However, imaging may be deferred to the primary care setting.

ED management may include offloading strategies with crutches or walkers, compression wraps, rest, anti-inflammatories, and consideration of referral for physical therapy. Patients should be directed to follow up with a primary care physician, podiatrist, or orthopedist.

ACHILLES TENDONITIS

Achilles tendonitis or tendonopathy is caused by overuse and is seen most commonly in middle-aged or older recreational athletes, especially with recent changes in activity level, training duration, running surface, or footwear. High body mass index has also been implicated as playing a role in the development of this condition (12). Inflammation or tissue degeneration and disorganization of the tendon results in pain 2 to 6 cm above the tendon insertion (13). Tenderness anterior to the tendon is more consistent with retrocalcaneal bursitis. Treatment includes rest, ice, heel lifts, eccentric exercises, NSAIDs, low-energy shock wave therapy, and, rarely, injection, laser therapy and surgery (13).

RETROCALCANEAL BURSITIS

Retrocalcaneal bursitis is an inflammation of the bursa that lies between the Achilles tendon and the posterior border of the calcaneus. Symptoms begin early in activity and are exacerbated by dorsiflexion of the foot. Tenderness is just anterior to the Achilles tendon (deep) and posterior to the calcaneus. Hind foot swelling is often present. The treatment is rest and administration of NSAIDs. The patient is instructed on stretching exercises and use of a heel lift. This condition can also be treated with steroid and local anesthetic injections.

PLANTAR FASCIITIS

The plantar fascia is a band of connective tissue on the plantar surface of the foot that extends from the calcaneal tuberosity to the

metatarsal heads. Plantar fasciitis is the most common cause of inferior heel pain and the etiology is not clearly understood but felt to be multifactorial in origin (14). Irritation and microtears due to overuse and repetitive heel strikes cause degeneration of the fascia, resulting in heel pain. The pain occurs often in the morning or with prolonged sitting. It is believed to be a degenerative process without inflammation. This entity accounts for 10% of running injuries and primarily afflicts the middle-aged, the elderly, and athletes. Physical examination findings include (a) point tenderness over the medial calcaneal tuberosity, (b) reproduction of pain with passive dorsiflexion of the ankle or toes, or (c) heel pain with standing on the toes.

ED management is focused on relaxing the tension on the fascia and includes rest, ice, stretching exercises, arch support, avoidance of aggravating activities, use of orthotics, administration of NSAIDs, dorsiflexion night splints, advising the patient to wear proper shoes, ultrasonic shockwave therapy, and rarely surgery (14–16).

MORTON&RSQUO;S INTERDIGITAL NEUROMA

Morton's neuroma is a common source of forefoot pain due to a degenerative neuropathy from repetitive trauma compressing the interdigital nerve, most often between the third and fourth metatarsal heads. It is seen in patients who are runners, dancers, and basketball players, and in those who have to stand for long periods of time or wear high-heeled shoes. Symptoms are sharp, stabbing pain and paresthesia between the toes.

The diagnosis is made clinically by pinching between the metatarsal heads and simultaneously using the other hand to compress the forefoot with pressure on the first and fifth metatarsal heads. This maneuver will elicit pain and possibly a palpable mass or an audible click, known as *Mulder click*. Treatment includes ice in acute cases, orthotics, rest, steroid injections, and possible surgical excision (17).

Common Pitfalls

- Failure to aggressively manage diabetic patients with foot disorders. The risk of complications is high if such patients are inadequately treated.
- Failure to recognize metatarsal stress fractures, which are common and may not be visualized radiographically in the acute setting. Suspected stress fractures are treated with avoidance of weight bearing.
- Failure to distinguish between plantar warts and calluses.

CHAPTER 150 Monoarticular Arthritis

Alan C. Heffner

Acute joint pain is a common emergency condition that carries a broad differential diagnosis. Trauma and crystal disease are the most common causes, while bacterial infection carries the greatest potential for morbidity and mortality. Arthrocentesis and synovial fluid analysis are key steps in the evaluation of acute monoarticular arthritis.

CLINICAL PRESENTATION

Acute arthritis typically presents with joint pain and swelling. The onset and severity of inflammation varies greatly depending on etiology and host factors such as age, comorbid disease, and immunocompetence. This chapter focuses on the most important types of monoarticular arthritis including crystal and infective arthropathies. Septic arthritis is divided into gonococcal and nongonococcal disease, reflecting the varied pathogenesis and management of these diseases.

Gonococcal Arthritis

Neisseria gonorrhoeae remains a common cause of septic arthritis in young, healthy, sexually active adults in the United States. Disseminated gonococcal infection (DGI) should be suspected in any sexually active patient with joint complaints. Women are more frequently affected than men and are predisposed to systemic spread during pregnancy and the perimenstrual period. DGI presents in two distinct patterns. The first is an acute suppurative monoarthritis

involving the knee, wrist, or ankle that occurs in 40% of DGI patients. Polyarthralgias may precede localization to a single joint. The second pattern is the gonococcal arthritis–dermatitis syndrome. Hematogenous spread of bacteria and immune complexes underlie the triad of *dermatitis, tenosynovitis,* and *migratory polyarthritis.* The classic skin lesions are scattered small painless erythematous macules or petechiae, which evolve into pustular to necrotic lesions on an erythematous base. Transient painful extensor tenosynovitis often involves the wrists, hands, and ankles but asymmetric migratory extremity polyarthralgias are the most common. Toxicity varies greatly in DGI. Patients can experience only mild constitutional symptoms and fever is often absent. Symptoms of primary genital infection may be absent.

Nongonococcal Septic Arthritis

Nongonococcal septic arthritis is a medical emergency due to the potential for rapid joint destruction and clinical sepsis. Permanent joint damage complicates 40% of septic joints and overall mortality is 15% but reaches as high as 50% in some subgroups (1,2). Large weight-bearing joints such as the knee and hip are most commonly involved, with the shoulder, ankle, elbow, and wrist occurring with decreasing frequency. Any articular surface may be affected including sternoclavicular, acromioclavicular, and sacroiliac joints.

Pathogenesis of nongonococcal septic arthritis involves one of four mechanisms: hematogenous seeding, contiguous spread, direct traumatic implantation, or postoperative invasion of prosthetic hardware. Hematogenous seeding of the vascular synovium is the most common source of septic arthritis. Bacteremia may stem from IV drug use, indwelling vascular access, recent invasive procedures, and distant active or recent infection. Contiguous spread into a joint occurs from adjacent cellulitis, tenosynovitis, osteomyelitis, or abscess. Examples include diabetic foot infections and pediatric metaphyseal osteomyelitis. Direct joint inoculation occurs with trauma or iatrogenically; the clenched fist “fight bite” injury and cat bites to the hand and wrist are commonly overlooked injuries.

Local factors such as antecedent arthritis, joint surgery or trauma, intra-articular steroid injections, and prosthetics predispose patients to septic arthritis. The risk of septic arthritis is severalfold higher in patients with underlying rheumatoid arthritis (1,3). Infections complicate up to 2% of prosthetic joint procedures, with revision arthroplasty carrying even greater risk. Pain localized to a prosthetic joint may signify mechanical loosening, prosthesis failure, or joint infection. Crystal-induced arthritis is rare in prosthetic joints.

Nongonococcal septic arthritis classically presents with rapidly progressive joint pain and swelling. Chronic illness and immunocompromise increase the risk of septic arthritis but also moderate the presenting symptoms. Insidious clinical progression in the absence of systemic toxicity is common in this group. Polyarticular involvement occurs in 10% to 20% of patients (4).

Gram-positive cocci remain the major nongonococcal pathogens in adults. *Staphylococcus aureus* is the most common causal organism, followed by streptococci including *Streptococcus pneumoniae.* Gram-negative bacilli including *Pseudomonas aeruginosa* cause 20% of infections and occur predominantly in immunocompromised patients and IV drug users. Anaerobes are isolated in a minority of cases but are more common with penetrating trauma. Inoculation of oral flora occurs in penetrating bite wounds. Mycobacterial and fungal arthritis are uncommon but important considerations in immunocompromised patients and those presenting with subacute progressive pain of the spine or weight-bearing joints.

Crystal-Induced Monoarthritis

Crystal-induced acute arthropathy is more common than septic arthritis and represents the most important mimic of infection. Gout and pseudogout may be clinically indistinguishable from septic arthritis. In both disorders, patients may demonstrate systemic symptoms, including fever.

Gout develops when monosodium urate (MSU) crystals precipitate within joints and trigger an acute inflammatory reaction. The

typical presentation is a middle-aged man with severe joint pain, swelling, redness, and warmth that evolves rapidly over hours to days. The initial attack is monoarticular in 85% of cases. Although any joint may be affected, the first metatarsophalangeal (MTP) joint (podagra) is involved in 60% of cases, followed by ankle, midfoot, and knee. Left untreated, gout follows a course of increasingly frequent attacks separated by shorter intercritical periods. Recurrent exacerbations cause chronic arthritic changes with bony erosions resembling rheumatoid arthritis or degenerative joint disease. Noninflammatory soft tissue tophaceous deposits may develop in the Achilles tendon or extensor surface of the fingers, forearms, or elbows. Common precipitants of acute attacks include increased purine intake, enhanced cellular breakdown (i.e., chemotherapy), alcohol, and joint trauma. In contrast to the classic presentation, older men and postmenopausal women may present with subacute to chronic polyarticular synovitis involving the small joints of the hands and feet. This presentation, resembling rheumatoid arthritis, is strongly associated with diuretic use and renal insufficiency.

Pseudogout is the result of calcium pyrophosphate dihydrate (CPPD) crystal deposition and manifests three common clinical courses: (1) asymptomatic radiographic stippling of articular cartilage (chondrocalcinosis), (2) acute attacks of mono- or oligoarticular inflammatory arthritis (pseudogout), and (3) progressive degenerative joint changes similar to osteoarthritis. Pseudogout usually develops after age 50 and may involve single or multiple joints, especially the knees, wrists, ankles, and elbows. Acute attacks may exhibit abrupt onset and marked discomfort, clinically indistinguishable from gout or septic arthritis. More commonly, the exacerbations evolve over days. Systemic illnesses including surgery or trauma are common triggers. Most cases are idiopathic, but CPPD deposition is associated with hyperparathyroidism and hemochromatosis.

DIFFERENTIAL DIAGNOSIS

Acute monoarthritis occurs with inflammatory, infectious, ischemic, neoplastic, traumatic, mechanical, or hemorrhagic processes (Table 150.1). The major diseases to consider include septic arthritis, crystal arthropathy, and trauma, but many disorders may produce pain, swelling, and erythema in or around a joint.

TABLE 150.1
Differential Diagnosis of Acute Monoarticular Arthritis

Infectious

Gonococcal

Nongonococcal

Mycobacterial (*M. tb* and atypical)

Spirochete (Lyme, syphilis)

Fungal

Peri- and postinfectious viral: HIV, hepatitis B, rubella, parvovirus, others

Crystal-Induced

Gout (MSU)

Pseudogout (CPPD)

Calcium apatite

Traumatic

Fracture

Ligamentous injury

Overuse injury

Ischemic

Avascular necrosis

Vasoocclusive crisis

Decompression illness

Spontaneous osteonecrosis

Hemorrhagic

Posttraumatic

Hemophilia

Systemic anticoagulation

Neoplastic

Metastasis

Osteochondroma

Osteoid osteoma

Pigmented villonodular synovitis

Systemic Disease

Remote infection, infectious endocarditis

Rheumatic fever

Seronegative spondyloarthropathies (Ankylosing spondylitis, enteropathic, psoriatic and reactive arthritis)

Reiter syndrome, Behcet disease

Rheumatoid arthritis, Systemic lupus erythematosus

Sarcoidosis, amyloidosis

Serum sickness

Periarticular conditions such as cellulitis, tendonitis, and bursitis must be distinguished from intra-articular pathology. Enthesitis is localized to tendinous insertions to bone. Bursitis results in pain and swelling overlying bony prominences. Most cases are noninfectious but septic bursitis may occur in the setting of local trauma; the olecranon and prepatellar bursas are the most commonly infected.

A variety of classically polyarticular inflammatory conditions including *rheumatoid arthritis, seronegative spondyloarthropathy, systemic lupus erythematosus,* and *postinfectious arthritis* may present with acute monoarticular symptoms. The seronegative arthritides, characterized by the absence of rheumatoid factor, include *ankylosing spondylitis, psoriatic arthritis, enteropathic arthritis* (associated with inflammatory bowel disease), and reactive arthritis (such as *Reiter syndrome*). Sterile postinfectious arthritis may be triggered by preceding or coincident infection with a variety of agents including Group A streptococci, HIV, parvovirus, hepatitis B, and rubella. Serum sickness and endocarditis are additional considerations.

Lyme disease manifests musculoskeletal features ranging from acute episodic arthralgia to chronic mono- or oligoarticular arthritis. Knee involvement is common. A history of tick exposure, travel to an endemic region, or erythema migrans rash is helpful but not always present.

Vascular compromise may lead to bone infarction and osteonecrosis. The weight-bearing surface of the femoral head and medial condyle of the knee are common locations. Patients complain of severe pain in the absence of trauma. Precipitants include sickle cell vasoocclusive disease, vasculitis, decompression illness, posttraumatic injury (i.e., hip dislocation), and corticosteroid-induced avascular necrosis.

Traumatic joint injuries are common. Development of an immediate joint effusion after injury suggests hemarthrosis due to ligamentous disruption or osteochondral fracture. Hemarthrosis may occur spontaneously or after minor trauma in the setting of coagulopathy due to anticoagulation or hemophilia. Osteoarthritis is a chronic, slowly progressive disease affecting weight-bearing joints.

Acute exacerbations may coincide with new or worsening effusion following overuse or minor trauma. Neoplastic lesions present with pain or pathologic fracture.

Children who present with a limp or refusal to walk may have septic arthritis or *acute transient synovitis*. Transient synovitis is the most common cause of hip pain in children 3 to 10 years of age. This self-limited inflammatory condition typically presents 1 to 3 weeks after a viral illness. There is considerable overlap in the clinical presentation of septic arthritis and transient synovitis. Consider slipped capital femoral epiphysis (SCFE) in a portly pubescent child and *Legg–Calve–Perthes disease* (aseptic necrosis of the femoral head) in young school-age children (see Chapter 242).

ED EVALUATION

Septic arthritis poses risk of joint destruction and even death if treatment is delayed. For this reason, the emergency evaluation of any joint complaint focuses on excluding infection. Assessment centers on history, physical examination, and arthrocentesis when indicated. Serum inflammatory markers are rarely informative and may mislead the physician if used as a substitute for arthrocentesis.

The temporal course, duration of symptoms, and history of similar joint symptoms should be clarified; acute and acute-on-chronic presentations deserve special attention. A history of recurrent monoarthritis or typical podagra suggests crystal-induced or other noninfectious arthritis. However, acute symptoms in patients with pre-existing arthritis deserve special attention, as antecedent joint pathology predisposes to infection (3,4). Atypical or marked exacerbations of chronic arthritis also warrant a high suspicion for superimposed infection. Acute worsening should not be attributed to progression of disease until infection is excluded. Rheumatoid arthritis carries a 10-fold higher incidence of septic arthritis and greater mortality compared to the general population; delayed diagnosis contributes to this poor outcome.

The degree and distribution of joint involvement separates arthritis into mono-, oligo- (less than three joints), and polyarthritis

patterns. Unless prompted, patients may complain only of a single painful joint, to the exclusion of other symptoms. Constitutional symptoms and morning stiffness are classically associated with rheumatic diseases.

A focused history should include comorbid diseases, especially immunosuppression. Immunomodulating drugs and antibiotics blunt the clinical presentation of acute infection. Potential septic sources include recent infection, invasive procedures, IV drug use, sexually transmitted diseases (STDs), and tick exposure. Genital ulcerations or discharge occur with gonococcal disease or Reiter syndrome. Rash, oral ulcers, uveitis, urethritis, and diarrhea suggest reactive arthritis. Medications should be reviewed with attention to precipitants of crystal arthropathy, such as diuretics. Infection following intra-articular injection is uncommon (2,5). Recent trauma suggests a fracture or musculotendinous injury but even minor trauma can precipitate gout. Penetrating injuries may introduce infection.

Examination begins with general assessment of toxicity and hemodynamic stability. Sepsis and shock may complicate infectious arthritis. Systemic findings including fever are not reliable to confirm or exclude septic arthritis. Fever is absent in up to 50% of patients with septic arthritis (6). Extra-articular sources of infection including cellulitis, pneumonia, genitourinary infection, and indwelling vascular access should be investigated as potential sources of bacteremic joint seeding. Cellulitis overlying a joint prosthesis increases the risk for joint involvement (7). Skin examination for disseminated gonococcal lesions is important. Oral ulcers may be present in Behcet syndrome, Reiter syndrome, and systemic lupus erythematosus. Oral thrush suggests immunosuppression. Infectious endocarditis commonly manifests with musculoskeletal symptoms and should be considered in any patient with a murmur and arthritis. Acute rheumatic fever and systemic lupus may also present this clinical picture.

Examine all joints to classify the number, degree, and symmetry of joint involvement. Resting position provides important clues to intra-articular pathology. The inflamed hip is often flexed and

externally rotated. An irritable knee is held in mild flexion. Testing active and passive range of motion distinguishes intra-articular from periarticular conditions such as bursitis, tendonitis, strain/sprain, and cellulitis. Pain on gentle motion, whether active or passive, is the hallmark of joint inflammation. *Patients with intra-articular pathology typically experience pain with any range of motion.* Refusal to move is common in severely inflamed joints. In contrast, periarticular conditions produce focal inflammation and localized tenderness without the same limited passive movement. Deep axial joints are difficult to evaluate. Pain localized to the sacroiliac joint may be exacerbated with the FABER maneuver (placing the hip into forced flexion, abduction, and external rotation).

The etiology of acute monoarthritis is difficult to diagnose by history and examination alone (6). Synovial fluid analysis is the diagnostic cornerstone for acute arthritis discrimination. Arthrocentesis should be performed in all cases of acute monoarticular arthritis, with the possible exception of classic recurrent gout. The emergency physician can safely aspirate most peripheral joints, but deep joints such as the hip and sacroiliac may require specialist consultation and fluoroscopic or ultrasound guidance. Orthopedic consultation is advisable before arthrocentesis of prosthetic joints.

Synovial fluid samples should be analyzed for cell count with differential, Gram stain, culture, and light microscopy for crystals. These tests require a minimum of 2 mL of fluid. *Culture and light microscopy for crystals are the most informative tests if fluid is limited* (8). Synovial fluid chemistries including lactate dehydrogenase (LDH), glucose, protein, and lactate are rarely helpful and may be misleading.

Synovial fluid leukocyte count distinguishes inflammatory versus noninflammatory effusions. Normal synovial fluid is clear, straw-colored, and highly viscous, with <200 WBC/mm^3. Leukocyte counts $<2{,}000$ WBC/mm^3 are considered noninflammatory and occur in osteoarthritis and chronic or inactive inflammatory diseases. More than 2,000 WBC/mm^3 indicates an inflammatory process. The synovial fluid of septic arthritis is classically opaque to

purulent with leukocyte counts >50,000 WBC/mm^3. However, the synovial leukocyte count must be interpreted with caution. The likelihood of infection increases with progressively greater synovial WBC count, but 40% of patients with nongonococcal infection have <50,000 WBC/mm^3 (9,10). Early infection, prior antibiotics, and immunocompromise (including immunosuppression) contribute to low leukocyte counts in the setting of infection. Predominance of polymorphonuclear cells (especially >90%) also suggests infection (6). Elevated leukocyte count is not specific for infection; rheumatoid and crystal arthropathy may induce vigorous inflammatory responses.

Gram stain may confirm infection but a negative stain does not exclude infection as it is diagnostic in less than 50% of cases. *Culture should be performed on all diagnostic synovial aspirates.* Synovial fluid culture is also imperfect. Direct inoculation of joint fluid into blood culture bottles and onto chocolate agar medium enhances organism yield. Potential sources of primary infection (i.e., blood and urine) should be cultured. Suspected DGI cases also warrant genital tract, oropharynx, rectum, and skin lesion cultures. Infection in these locations may be asymptomatic. Fungal and mycobacterial cultures are warranted in patients at risk.

Polarized light microscopy is the gold standard for crystal identification. MSU appears as needle-shaped or elongated crystals exhibiting brilliant negative birefringence. The rhomboid or rod-shaped crystals of CPPD are more difficult to visualize under white light and display weak positive birefringence. Differentiating intracellular and extracellular crystal formations is not diagnostically helpful. Because of interobserver variability, repeat examination is warranted when initial microscopy is inconclusive and clinical suspicion of crystal disease remains high (8). Septic arthritis is generally excluded by confirmation of an alternative diagnosis such as crystal arthropathy. Although rare, concomitant septic and crystal arthritis is described in 1.5% of cases (11–13).

Blood tests rarely aid in the diagnosis of acute monoarthritis (6). Inflammatory markers including WBC count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and

procalcitonin do not discriminate infective arthritis (7). Peripheral leukocytosis is present in half of patients with septic arthritis, and patients with acute gout can have significant leukocytosis (9). Acute-phase reactants such as ESR and CRP are common in bacterial arthritis but also rise in noninfectious disease. Serial acute-phase reactants are sometimes used to follow therapeutic response in established infection. Serum uric acid levels are likewise discouraged, as they do not correlate with acute gout symptoms (5). *In short, blood tests are often unhelpful or misleading in attempts to exclude septic arthritis.*

Radiography yields little in the evaluation of acute nontraumatic monoarthritis. Plain films are commonly normal or reveal nonspecific soft tissue swelling or joint effusion in the setting of inflammation. Joint space narrowing, periarticular osteoporosis, and erosive osteomyelitis caused by infection occur over days to weeks. Neonates rarely manifest joint dislocation or subluxation in the setting of infection. Chronic or recurrent gout may induce joint space narrowing and juxta-articular bony erosions with overhanging edges. Linear stippling and punctate densities of articular cartilage such as the menisci or triangular ligament of the radioulnar joint identifies chondrocalcinosis of CPPD but does not exclude other disease. Prosthetic loosening may be evident on plain films but does not differentiate mechanical failure from infection. Radiographs in patients with subacute to chronic symptoms should be scrutinized for fracture, foreign body, avascular necrosis, loose joint bodies, chronic joint changes, osteomyelitis, tumor, Paget disease, and osteochondritis desiccans among other processes.

Advanced imaging with ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) can differentiate articular from periarticular soft tissue processes and is sensitive for joint effusions. This is particularly helpful in difficult-to-examine joints such as the hip, sternoclavicular, and sacroiliac joints. Unfortunately, these techniques do not distinguish infected from sterile joint fluid.

KEY TESTING

- Arthrocentesis, with synovial fluid analysis for:
- Cell count with differential, Gram stain, culture, light microscopy for crystals
- If the synovial fluid sample is limited, culture and light microscopy for crystals are the most helpful tests.

ED MANAGEMENT

Gonococcal Arthritis

Initial therapy for disseminated gonococcal disease is a parenteral third-generation cephalosporin; alternative regimens include spectinomycin. Empiric therapy for concurrent chlamydia infection is also required.

Septic Arthritis

Rapid diagnosis and therapy is important to prevent joint and systemic morbidity of septic arthritis. Treatment requires appropriate antibiotics and surgical source control in most cases. As with any infectious process, begin antibiotics immediately after appropriate culture collection if the diagnosis is highly suspected. Antibiotic selection is based on the clinical probability of a specific pathogen as determined by patient presentation, age, comorbid risks, and Gram stain. Empiric broad-spectrum parenteral antibiotics are indicated in most situations (Table 150.2). Although primary pathogens are somewhat dissimilar, combination therapy with vancomycin and a third-generation cephalosporin are appropriate for most adults and children. The growing incidence of methicillin-resistant *S. aureus* (MRSA) warrants empiric coverage for this agent (14). Patients with gram-negative bacilli identified on stain and those at high risk for these pathogens warrant broadened empiric coverage. Intra-articular antibiotics provide no additional value for septic arthritis and carry the risk of chemical synovitis. Removal of infection and inflammatory debris is an essential component of treatment. Closed needle aspiration versus open surgical drainage of septic joints is controversial and should be left to the discretion of

the orthopedic consultant. Adjunctive systemic steroids to reduce the inflammatory response following infection control remains under investigation.

TABLE 150.2
Treatment of Monoarticular Arthritis[a]

Type	Example Regimen (Pediatric Dose)	Alternative Regimen
Infectious		
Empiric and non-GC	Vancomycin (20 mg/mg or 2 g max dose) q8–12h IV *and* Third-generation cephalosporin Ceftriaxone 2 g qd (50 mg/kg qd) Cefotaxime 2 g q8h (50 mg/kg) Ceftazidine 2 g q8h (50 mg/kg) Patients at risk for gram-negative organisms warrant broadened empiric coverage for these organisms	Linezolid 600 mg IV q12h Levofloxacin 750 mg IV 24h
Isolated GC	Ceftriaxone 1 g qd Cefotaxime 1 g q8h Ceftizoxime 1 g q8h Treat empirically for concurrent chlamydia[a]	Spectinomycin 2 g IV q12h
Crystal-Induced	NSAID Naproxen 500 mg PO bid for 5 d Indomethacin 50 mg PO tid. for 3 d and taper over 4–7 d (or comparable NSAID) Acetaminophen and narcotic analgesics as needed	Corticosteroids Prednisone 30 mg PO qd for 5 d Methylprednisolone 40–60 mg IV q8–12h Triamcinolone 60 mg IM Methylprednisolone 5–40 mg IA Colchicine 0.6 mg PO q1h for up to three doses
Traumatic	Joint aspiration for tense effusion Rest, ice, compression, elevation (RICE) Orthopaedic follow-up as needed	
Hemorrhagic	Correct coagulopathy RICE	
Inflammatory	Naproxen 500 mg PO bid (or comparable NSAID) High-dose ASA for RA Acetaminophen and narcotic analgesics as needed	

[a]See text for details.
ASA, acetylsalicyclic acid; IM, intramuscular; RA, rheumatoid arthritis; PO, per os (by mouth).

Crystal-Induced Arthritis

Although acute crystal-induced arthritis is generally self-limited, treatment relieves discomfort and prevents progressive joint destruction (Table 150.2). Nonsteroidal anti-inflammatory drugs (NSAIDs) are the historic treatment of choice for most patients. High initial dosing typically provides marked relief within 24 hours and may be tapered as symptoms improve to reduce potential adverse effects. The usefulness of NSAIDs is limited by their side effects including gastropathy, renal dysfunction, and interaction with warfarin.

Systemic corticosteroids are an important alternative. Comparable efficacy and safety in acute gout supports first-line use of glucocorticoid therapy, especially for patients with contraindication or suboptimal response to NSAID therapy (15–17). Oral, IV, and intramuscular options are available. Intra-articular steroids are very effective for crystal disease but their use requires the confident exclusion of infection. The appropriate intra-articular steroid dose is dependent on joint size; 20 to 40 mg of methylprednisolone acetate is adequate for larger joints such as the knee, whereas 5 to 10 mg is appropriate for smaller joints.

The leukocyte inhibitor colchicine provides dramatic relief of gout if utilized within 24 hours of onset but use has declined due to its narrow therapeutic window and higher risk of adverse effects. While traditional dosing was higher, a newer, more conservative recommendation is to administer 0.6 mg/hr up to three doses (1.8 mg total). Patients should not take additional colchicine for 7 days following an oral load. IV colchicine carries increased risk of systemic toxicity and is not recommended. Elderly patients and those with renal and hepatic dysfunction are not candidates for colchicine.

Serum urate-lowering agents such as allopurinol and probenecid are contraindicated in the setting of acute or resolving gout. The resultant change in serum urate may exacerbate or prolong an attack. Joint rest and cold applications provide symptomatic relief.

Warm compresses exacerbate joint inflammation and should be avoided. Acetaminophen and narcotic analgesics provide additional relief if needed.

CRITICAL INTERVENTIONS

- Initiate early parenteral antibiotic therapy for patients with septic arthritis.

DISPOSITION

Gonococcal arthritis is typically responsive to antibiotics and may not require surgical drainage. Reliable nontoxic patients with gonococcal disease of nonweight-bearing joints may be treated as outpatients with daily parenteral therapy and close monitoring. Clinical improvement should occur within 48 hours at which time patients may be transitioned to oral therapy. Counseling includes discussion of STDs, birth control, partner counseling, and referral for HIV and syphilis testing. Patients with nongonococcal or undifferentiated septic arthritis require hospitalization. Most patients with acute gout can be successfully treated as outpatients. Precipitating factors such as alcohol use, purine-rich foods, and diuretics should be addressed.

Common Pitfalls

- Failure to consider infection in patients with acute worsening of pre-existing arthritis.
- Failure to obtain synovial fluid for analysis.
- Excluding septic arthritis based on absence of fever or normal serum inflammatory markers.
- Ordering protein and glucose on synovial fluid.
- Failure to perform culture on all diagnostic synovial fluid specimens.
- Inadequate empiric antibiotic selection in cases of suspected infection.
- Failure to recognize the migratory polyarthritis and tenosynovitis of disseminated gonorrhea.

- Diagnosing or excluding gout based on the serum urate level.
- Prescribing serum urate–lowering agents during an acute gout attack.

CHAPTER 151

Polyarticular Arthritis

Richard S. Hartoch

Polyarticular arthritis presents as an acute or chronic inflammatory synovitis (synovial warmth, swelling, and tenderness) developing at a minimum of two joints. The emergency physician encounters polyarthritis in two contexts: the patient without a known rheumatologic disease who presents with multiple painful joints, and the patient with complications of a previously diagnosed condition, most commonly rheumatoid arthritis (RA).

CLINICAL PRESENTATION

Many polyarthritis syndromes have a gradual onset and may defy precise diagnosis despite extensive initial workup. Symptoms of early hepatitis C, systemic lupus erythematosus (SLE), RA, and other collagen–vascular diseases overlap and laboratory test results may be equivocal. A definitive diagnosis may not readily be made on a single emergency department (ED) visit. Although the syndromes share arthritis as a common feature, all have associated symptoms that are helpful in evaluation (Table 151.1). A thorough history and physical examination may be the most important tools in establishing a diagnosis.

TABLE 151.1
Polyarticular Arthritis: Clinical Features

Rheumatoid Arthritis

Symmetric, additive involvement initially of small joints, especially MCP, PIP, and wrists

Morning stiffness, positive rheumatoid factor in 75%

Acute Rheumatic Fever

Migratory polyarthritis, carditis, erythema marginatum, subcutaneous nodules, chorea

Gonococcal Arthritis

Tenosynovitis, characteristic rash

Lyme Disease

Brief, recurrent; involves knees, preceded by characteristic rash

Erythema chronicum migrans, cardiac and neurologic involvement, Bell palsy

Reactive Arthritis (formerly Reiter Syndrome)

Asymmetric involvement of lower extremities

Urethritis, conjunctivitis, skin lesions

Viral Arthritis

Symmetric involvement of fingers, wrists, and knees

Serum Sickness

Migratory involvement of large and small joints; associated rash

Systemic Lupus Erythematosus

Multiple organ system involvement

Symmetric evanescent involvement of any joint

Serologic markers—ANA (sensitive), anti-dsDNA (diagnostic)

Osteoarthritis

Lower extremity involvement

Heberden nodes

Lack of inflammatory signs

Ankylosing Spondylitis

Insidious involvement of spine (occasionally hips and shoulders)

Uveitis in 25%; HLA-B27 positive (90%)

Colitic Arthritis

Large joints

Parallels course of ulcerative colitis or regional enteritis

Psoriatic Arthritis

Distal interphalangeal joint involvement

Symmetric or asymmetric

Skin disease begins first; 80% have pitting of nails

Rheumatoid Arthritis

The most commonly encountered etiology of polyarthritis is RA, characterized by symmetric joint inflammation, constitutional symptoms, and in some cases, extra-articular organ involvement. The disorder ranges in severity from a mild nonprogressive arthritis to a fulminant, sometimes fatal, illness with destruction of joints and serious systemic involvement. Early recognition and initiation of appropriate therapy generally results in an improved outcome. A majority of patients who have been newly diagnosed with RA will experience remission if aggressively treated by a rheumatologist.

The onset of RA may be acute or insidious. Inflammation in multiple joints in almost any combination may be present, although symmetric inflammation of the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints and wrists is most common. The vast majority of RA patients will complain of pain when their four MCP joints are gently squeezed together. RA virtually never affects the thoracic or lumbar spine. Systemic manifestations include malaise, anorexia, fever, myalgias, and weight loss. In some patients, especially those with high titers of rheumatoid factor and more severe joint disease, there is systemic organ involvement, most commonly lungs and heart.

Acute Rheumatic Fever

Although the incidence of acute rheumatic fever (ARF) has dramatically declined over the past 40 years, recent reports have described episodic outbreaks. The diagnosis of ARF mandates fulfillment of the modified Jones criteria (Table 151.2). Arthritis, the most common finding in ARF, is seen in more than 75% of first attacks. It is typically migratory and most often first affects the large joints of the lower extremities, knees, and ankles, followed by wrists and elbows. Each joint is inflamed for up to 1 week. Carditis, clinically seen in 40% to 50% of acute cases, is the most serious finding. Recent echocardiographic studies have revealed that the carditis is often subclinical and present to varying degrees of severity in virtually all patients with ARF. The patient may present

with pleuritic chest discomfort, a new murmur (usually mitral regurgitation), cardiomegaly, and possibly congestive heart failure. Chorea occurs in 5% of cases. It develops several months after streptococcal infection and is characterized by emotional disturbances, weakness, and sudden involuntary movements that cease with sleep. *Erythema marginatum* (5% of cases) begins as a macule that extends outward with central clearing. It may resemble erythema chronicum migrans, the rash of Lyme disease (LD). It is not painful or pruritic. It usually fades within hours but may recur. Subcutaneous nodules, seen in <10% of patients, are firm, painless, and of variable size (2 to 10 mm). They are most commonly seen over the extensor joint surfaces or bony prominences.

TABLE 151.2
Modified Jones Criteria for Diagnosis of Acute Rheumatic Fever

Major Criteria	Minor Criteria
Carditis	History of acute rheumatic fever
Polyarthritis	Fever
Chorea	Arthralgia
Erythema marginatum	Elevated sedimentation rate
Subcutaneous nodules	Prolonged PR interval

Note: The diagnosis of acute rheumatic fever requires two of the major criteria or one of the major criteria and two of the minor criteria plus evidence of recent group A streptococcal pharyngitis (positive culture or increased ASO titer).

Poststreptococcal reactive arthritis (PSRA) is a clinical syndrome with insufficient Jones criteria to be called ARF. Consider obtaining an antistreptolysin O (ASO) titer. Treat strep pharyngitis with antibiotic and arthritis with nonsteroidal anti-inflammatory drugs (NSAIDs). Prednisone may be indicated in severe cases.

Gonococcal Arthritis

Gonococcal arthritis (GA), although infrequently seen, is still the most common bacterial arthritis among healthy young people. It develops in 1% to 3% of patients with untreated gonococcal infection. Disseminated gonococcal infection (DGI) is characterized

by a clinical triad: dermatitis, tenosynovitis, and migratory polyarthritis. Joint involvement is predominantly asymmetric, often affecting the knee, ankle, elbow, and wrist. A painless, nonpruritic skin rash consisting of scattered papules or vesicles with a hemorrhagic or necrotic center is seen in roughly 50% of patients. HIV patients are infected in unusual joints (hip and sternoclavicular) and may develop a more aggressive course.

Lyme Disease

LD is caused by the spirochete *Borrelia burgdorferi,* transmitted by the bite of the deer tick, *Ixodes scapularis* (formerly *I. dammini*). A characteristic rash, erythema chronicum migrans, develops in 60% of patients. It starts as a single red macule that expands to form a large annular lesion with a red outer border and central clearing. Two weeks to 2 years after the initial skin lesion, 60% of patients develop an acute arthritis, typically asymmetric oligo- or monoarticular, involving large joints, most commonly the knee. About 10% of patients develop cardiac abnormalities, most often atrioventricular (AV) block. Although cardiac involvement is transient, some patients require temporary pacemakers. Approximately 10% of patients develop significant neurologic abnormalities, including meningitis, encephalitis, and cranial neuropathies, particularly facial nerve paralysis.

Reactive Arthritis

Reactive arthritis (formerly Reiter syndrome) may occur as a polyarthritis in young, often human leukocyte antigen (HLA) B-27–positive men. It classically presents as a triad of nongonococcal urethritis, asymmetric polyarthritis, and conjunctivitis. The arthritis is usually acute in onset, involving the large joints of the lower extremities, particularly the knees and ankles. Urethritis usually precedes the development of arthritis, although it may be asymptomatic and suggested only by the finding of white blood cells on microscopic examination of first-voided, morning urine. Conjunctivitis occurs in 30% of patients and iritis in 10%. Two

distinctive skin lesions are occasionally seen. *Keratoderma blennorrhagica* (15% of patients), scaling lesions on the palms and soles that begin as erythematous macules, may progress to lesions indistinguishable from those of psoriasis. *Circinate balanitis* (25% of patients) produce painless superficial ulcers of the glans penis. Reactive arthritis may be triggered by intestinal infections (*Salmonella, Shigella,* or *Campylobacter*) or sexually transmitted diseases (*Gonorrhea* or *Chlamydia*).

Viral Arthritis/Postinfectious Arthritis

Transient nondestructive arthritis has been associated with viral infection, the best documented being hepatitis A, B, and C and rubella. The arthritis of hepatitis is believed to be due to the deposition of circulating immune complexes in affected joints. It typically occurs during the prodrome of the illness before the appearance of jaundice. Liver enzymes are usually elevated, and HBsAg or anti-HBc may be positive. The most common presentation is that of a symmetric polyarthritis potentially involving the hand, wrist, elbow, and ankle. It can be painful with prominent morning stiffness but seldom lasts more than 3 weeks. The presentation of hepatitis C may easily be mistaken for RA.

Parvovirus has been implicated as the etiologic agent in an acutely painful polyarthritis involving hands, wrists, elbows, knees, and shoulders. Parvovirus, perhaps better known for its causative role in erythema infectiosum (fifth disease in children), may be detected by elevated IgM titers. The arthritis, often seen in patients who work with children, persists for several weeks and is generally responsive to NSAID therapy. Polyarthritis syndromes have also been described in association with enteric infections (*Yersinia, Shigella, Salmonella, Clostridium difficile*), respiratory infection (mycoplasma), and α-viruses outside US.

Serum Sickness

Serum sickness, typically occurring 6 to 10 days after an antigenic stimulus, presents with the abrupt onset of fever, lymphadenopathy,

and arthritis especially involving knees, ankles, shoulders, and wrists. Urticaria or angioedema may also develop. A more severe reaction tends to result after subsequent exposure to the same antigen. Penicillin is the most commonly implicated causal agent, but many other drugs including other α-lactams, ciprofloxacin, levoquin, angiotensin-converting enzyme inhibitors, and allopurinol have been implicated as well.

HIV Arthritis

Several polyarthritis syndromes have been described in association with HIV infection. A painful, asymmetric, oligoarticular arthritis affecting the knees and ankles has been widely reported. Also seen are seronegative spondyloarthritis and lupus-like syndromes. These polyarthritides may occur at any stage of HIV infection and have been reported to develop months or years before the actual diagnosis of HIV. Because of impaired immunity, HIV patients are at risk for pyogenic joint infections. *Streptococcus* and *Staphylococcus* sp predominate, but opportunistic pathogens may be involved.

DIFFERENTIAL DIAGNOSIS

There are numerous disorders that produce polyarticular arthritis, including RA, acute rheumatic fever, GA, LD, gout, postviral arthritis, septic arthritis, serum sickness, SLE, osteoarthritis, ankylosing spondylitis, ulcerative colitis, regional enteritis (Crohn disease), and psoriatic arthritis. Clinical features that may be helpful in distinguishing the disorders are listed in Table 151.1. Inflammation in the periarticular soft tissues (tendons, bursae, etc.) can cause swelling and limitation of motion, simulating joint disease. Arthritis generally affects both active and passive motion equally, whereas acute tendinitis or bursitis limits active motion significantly more than passive ranging.

ED EVALUATION

Sudden onset of joint pain (developing over several hours, rather than days) strongly suggests gout or infection. The most critical

joint disorder to consider and diagnose immediately is septic arthritis, which can cause rapid destruction and systemic illness. Although the classic presentation is single joint involvement in a febrile patient, 15% of cases of septic arthritis are polyarticular and 20% are afebrile. Patients with underlying joint disease, diabetes, alcoholism, and malignancy are at particular risk for polyarticular infection. These patients are often bacteremic and have inpatient mortality rates exceeding that of myocardial infarction.

The persistence of symptoms for over 4 to 6 weeks suggests a systemic rheumatologic disease. Symmetric joint involvement is seen in RA, hepatitis C, and SLE. Asymmetric joint involvement is typical of the seronegative arthritides (e.g., reactive arthritis and psoriatic arthritis). Migratory involvement (leaving one joint before involving another) is characteristic of acute rheumatic fever. A family history of arthritis supports a diagnosis of RA or one of the seronegative spondyloarthropathies. Thiazide and loop diuretics, alcohol, high protein intake, low-dairy diets, and obesity are linked with the development of gout, which may be polyarticular in presentation. Hydralazine, procainamide, isoniazid, phenytoin, and several tumor necrosis factor (TNF) inhibitors can induce a lupus-like reaction.

To assess patterns of involvement and chronicity, all joints should be examined, not just those that are symptomatic. A relatively rapid assessment can survey up to 60 joints. Several acute polyarthritides are associated with a characteristic rash. Subcutaneous nodules are seen in 35% of patients with RA and $<10\%$ of those with ARF. Psoriatic arthritis may be associated with pitting of the nails and the typical papulosquamous eruption. A general physical examination may note such important findings as a pleural effusion in SLE and RA or clinical signs of liver dysfunction in arthritis associated with hepatitis. A pelvic examination should be performed on all women with unexplained arthritis to rule out *Neisseria gonorrhoeae.* Generalized lymphadenopathy or thrush may suggest HIV.

The most important laboratory test is examination of the joint fluid. Usually obtained studies include white cell count with differential, Gram stain and culture, and examination for crystals.

Specific diagnostic tests (e.g., antinuclear antibody, rheumatoid factor, Lyme titer, HIV, hepatitis screen) are seldom available on an emergency basis. They should be ordered in appropriate patients for use in subsequent evaluation. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) can be elevated in any inflammatory condition. Such tests are generally of only marginal diagnostic assistance but may be useful in monitoring disease activity in patients with chronic arthritis. The diagnosis of ARF, which should be especially considered in children and young adults, requires laboratory confirmation of recent group A streptococcal infection. In patients with GA, arthrocentesis cultures are positive in only half of affected joints. Higher yield for positive culture may be obtained from the mucosal surface of initial infectious contact (throat, cervix, urethra, or rectum). Polymerase chain reaction (PCR) may be useful in identifying gonococcal infection from a joint that is culture-negative.

Radiographs are of limited utility in the evaluation of the patient with nontraumatic joint pain. Radiographically visible inflammatory changes (such as symmetric erosions of the wrist and MCP joints in RA) occur late in the course of disease. A normal radiograph does not rule out a diagnosis of arthritis.

Recent RA literature repeatedly stresses the importance of early diagnosis and prompt referral of suspected cases to a rheumatologist. Proper treatment, which involves the *very* early usage of disease-modifying antirheumatic drugs (DMARDs), yields a markedly improved long-term outcome. Delay of as little as 3 months in initiating therapy has been shown to result in significantly increased joint damage at 5 years. The diagnosis of RA is based largely on a high index of suspicion, a careful history, and directed physical examination. Rheumatoid factor, although not a specific marker for RA, is present in the serum of 75% of patients. Clinical criteria established by the American Rheumatism Association include prolonged morning stiffness, symmetric joint involvement, chronicity, rheumatoid nodules, and radiographs revealing erosions. Recent studies reveal that the characteristic bone erosions may be visualized by ultrasound and magnetic resonance

imaging (MRI) significantly earlier than by conventional radiography.

KEY TESTING

- Arthrocentesis with joint fluid analysis to exclude septic joint

ED MANAGEMENT

The management of polyarthritis depends on the correct diagnosis. Septic arthritis must be managed as an inpatient with IV antibiotics, orthopedic consultation, and discovery of the source of possible bacteremia. Suspected RA mandates *prompt* rheumatologic consultation for rapid initiation of DMARD therapy, usually methotrexate, biologic TNF inhibitors, biologic non-TNF inhibitors, or other agents. NSAIDs are *not* effective in limiting the destructive consequences of RA.

The mainstay of treatment for general, undiagnosed polyarthritis is NSAIDs. These agents control both pain and inflammation. If one NSAID fails to control symptoms, another in a different class may be more effective. All NSAIDs should be prescribed with caution, and patients should be monitored for adverse gastrointestinal effects, renal dysfunction, edema, and cardiac complications. NSAIDs should generally be taken with food.

TNF inhibitors are newer agents used in the treatment of RA. They are generally well tolerated, but the practitioner must be alert to clinically significant, potentially life-threatening side effects. TNF has antitumor and antiviral effects and has particular activity against intracellular pathogens, notably *Mycobacterium tuberculosis.* TNF stimulates inflammatory cells to areas of infection and may be involved in the formation of granulomas which contain TB. It plays an important role in modulating the systemic inflammatory response of sepsis.

Patients receiving TNF inhibition are subject to a variety of serious infections and may present to the ED appearing “less sick” than other patients with similar conditions. Particular issues include unrecognized sepsis with various bacteria, notably *Streptococcus*

pneumoniae and *Klebsiella.* One should also consider reactivation of TB, opportunistic infections including *Listeria, Legionella,* and disseminated fungal infections. These patients with their blunted immune response may not show expected signs and symptoms of severe infection. They may have a negative PPD test for TB due to anergy.

Several disorders require more specific treatment. Patients with a first attack of ARF should be hospitalized and closely monitored for worsening carditis, arrhythmias, and valve damage. High-dose salicylates and prednisone may be useful. The patient must be monitored for the development of congestive heart failure. A course of penicillin is recommended to eradicate any remaining streptococci, and the patient may be kept on low-dose penicillin prophylaxis indefinitely thereafter.

Most patients with GA should be hospitalized. Therapy is initiated with a parenteral third-generation cephalosporin. Because of recently described increased rates of GC resistance, fluoroquinolones may not be effective. Repeated joint aspirations, arthroscopy, or surgery may be required. In most cases, dramatic clinical improvement is noted in several days, and the patient may transition to oral antibiotics. Patients should be treated concurrently for chlamydia.

The arthritis associated with LD is generally treated for at least a month with doxycycline or amoxicillin. Resistant cases are treated with IV ceftriaxone. Reactive arthritis is not curable, but treatment of the initial urethritis may prevent development of the full-blown disease. Slit-lamp examination of the anterior chamber is essential to rule out associated iritis. Arthritic inflammation is treated symptomatically with NSAIDs.

Complications of RA

RA is the most common and most serious of the chronic polyarthritides and may be associated with a number of emergent complications (Table 151.3). The emergency physician should be aware of classic acute issues arising in patients with well-established

RA. RA patients are also at risk for toxic and immunosuppressive effects of treatments.

TABLE 151.3
Complications of Rheumatoid Arthritis

Organ	Manifestations
Neurologic	Subluxation C-1, C-2 (cord compression); entrapment neuropathy (carpal tunnel); peripheral neuropathy; myositis; necrotizing vasculitis (central nervous system)
Musculoskeletal	Septic arthritis; tendon rupture; synovial cyst knee (pseudophlebitis); rheumatoid nodules
Larynx	Cricoarytenoid arthritis (airway)
Lung	Pleurisy; effusion; fibrosis
Cardiac	ACS; sudden death; pericarditis; tamponade; conduction defects; valvular (nodules)
Hematologic	Anemia; leukopenia; hyperviscosity; Felty syndrome (splenomegaly, neutropenia)
Ocular	Sjögren syndrome; episcleritis; scleritis
Blood vessels	Vasculitis (usually dermal, can be widespread)

Cardiovascular disease (CVD) is one of the most common causes of death in patients with RA and occurs at a younger age than in the general population. Chronic inflammation as seen in RA, PA, and SLE results in accelerated atherosclerosis. RA patients with an acute coronary syndrome (ACS) are more likely to present to the ED with atypical symptoms. RA may be considered an independent risk factor for coronary artery disease, and in fact several studies reveal it to be as significant as diabetes or hypertension. The increased CVD risk may be present even before clinical evidence of RA develops. Aggressive efforts to control inflammation and modify traditional cardiac risk factors are particularly vital in these patients.

Radiographic abnormalities of the cervical spine are common, particularly subluxation of C-1 on C-2. Usually these abnormalities are asymptomatic, but the appearance of neurologic symptoms or signs necessitates neurosurgical consultation. Patients may note a peculiar slipping sensation with neck movements that is associated

with either exacerbation or relief of symptoms. A patient with RA who sustains even minor cervical trauma is at risk for serious injury. The potential for cervical spine instability should be considered when intubating a patient with chronic RA, and cervical spine precautions should be observed.

Various entrapment neuropathies occur in RA, of which carpal tunnel syndrome is the most common. Patients initially complain of sensory changes over the distribution of the median nerve and a "toothache-like" pain at the wrist. The diagnosis is confirmed with electromyography and nerve conduction studies. Treatment consists of splinting the wrist and arranging consultation with a rheumatologist, orthopedist, or neurologist. Local corticosteroid injection is occasionally useful. Surgical release of median nerve entrapment is sometimes necessary. Generalized muscle wasting, weakness, and peripheral neuropathy in RA patients may also be manifestations of systemic vasculitis.

Rupture of the extensor tendons of the hand is not uncommon in advanced RA. Once one tendon ruptures, the increased strain on the remaining tendons may lead to rupture of others. Patients cannot extend the fingers actively at the MCP joints, but passive extension is still possible. Treatment is elective surgical repair.

The development of a synovial cyst behind the knee is common in RA. Synovial inflammation may result in large knee effusions, and high pressure generated during flexion of the knee may cause cyst formation in the popliteal fossa. The diagnosis is confirmed by an arthrogram or ultrasound of the knee joint. Curative treatment is difficult. Joint aspiration and local corticosteroid injection may be temporarily helpful. These cysts may rupture, dissecting into the calf. The resulting calf pain, swelling, and redness may mimic the presentation of deep vein thrombosis. Duplex sonography is helpful in distinguishing these clinical entities.

The cricoarytenoid joint is a synovial articulation and can be involved in RA. Patients may present with stridor and significant airway obstruction, dyspnea, dysphagia, painful speech, foreign-body sensation, or hoarseness. There may be tenderness over the thyroid cartilage. Laryngoscopy reveals redness and edema over the

arytenoids and abnormal bowing of the vocal cords during inspiration. Intubation may be difficult. Cricothyrotomy or tracheostomy may be necessary to secure the airway. Corticosteroids and cool humidification are useful in milder cases.

The most common type of vasculitis associated with RA involves small dermal vessels, causing relatively benign infarctions in the periungual areas of the fingers. Occasionally patients develop a necrotizing vasculitis, which can follow a fulminant course. The presenting manifestations may be large ulcerations, digital gangrene, neuropathies, mesenteric ischemia, or coronary arteritis. Patients with systemic vasculitis usually have fever, leukocytosis, high titers of rheumatoid factor, an elevated ESR, and antinuclear antibodies. They should be admitted to the hospital for initiation of high-dose corticosteroids. At times cytotoxic agents or apheresis are useful. The prognosis in patients with extensive vasculitis is poor.

Sjögren syndrome (keratoconjunctivitis sicca), sometimes associated with RA, is characterized by dry eyes and dry mouth and is caused by decreased lacrimal and salivary gland function. Patients complain of grittiness in the eyes and thick mucus beneath the eyelids. The diagnosis is made by the Schirmer test which measures tear production. Treatment consists of artificial tears, humidified air, and eye goggles to minimize tear evaporation.

Episcleritis, also associated with RA, is usually benign but should be followed by an ophthalmologist because it can lead to *scleritis.* A brief course of topical corticosteroids as prescribed by an ophthalmologist is usually beneficial. Scleritis is a more diffuse process and can cause uveitis, glaucoma, and rupture of the globe. Patients complain of a deep aching sensation and tenderness on gentle palpation of the globe. Slit-lamp examination reveals cellular exudate in the anterior chamber. Prompt ophthalmologic consultation is indicated.

Hematologic problems, including anemia, leukopenia, and hyperviscosity, occur in RA. Felty syndrome (triad of RA, splenomegaly, and neutropenia) is associated with severe disease. These patients are prone to recurrent infections and have hepatic

dysfunction and recurring cutaneous ulcers. Splenectomy is occasionally beneficial.

Pleurisy and pleural effusions are common in RA but are not usually life-threatening. Pericarditis is also common, but only rarely does pericardial tamponade or constrictive pericarditis occur.

CRITICAL INTERVENTIONS

- Consider ACS in patients with RA, PA, and SLE.
- Consult a rheumatologist as soon as possible when RA is suspected.

DISPOSITION

Septic arthritis requires emergent intervention and inpatient management. Patients with a first attack of ARF should be hospitalized. Most patients with GA should also be hospitalized for initial therapy. LD in early stages is generally treated with doxycycline on an outpatient basis. Advanced cases may require hospitalization.

Patients with RA or SLE may present with complications requiring admission, but isolated nonseptic exacerbations of joint pain are often managed successfully on an outpatient basis. Admission decisions for other causes of polyarticular arthritis are often dependent upon the certainty of diagnosis, the adequacy of pain control, and the presence or absence of other disease complications.

Common Pitfalls

- Failure to analyze synovial fluid in a patient with new joint tenderness, warmth, and swelling.
- Failure to diagnose ACS in a patient with RA who presents with atypical symptoms.
- Failure to identify sepsis or a serious opportunistic infection in a patient on TNF inhibitor therapy.
- Failure to recognize an acute septic joint in a patient with underlying chronic polyarthritis.

- Failure to consider a diagnosis of RA, resulting in delayed diagnosis and treatment.
- Failure to consider acute rheumatic fever in a child or young adult.
- Failure to consider underlying HIV infection in a person with a newly diagnosed, seronegative spondyloarthropathy or lupus-like syndrome.

SECTION XV
Neurologic Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 152
Organic Brain Syndrome

Rebecca R. Roberts and Basem F. Khishfe

Patients in acute distress from mental health causes seek treatment in the emergency department (ED). EDs also provide medical evaluations prior to civil commitment for many patients in psychiatric crisis (1). The purpose is to detect the presence of medical illness complicating or causing psychiatric symptoms. Differentiating between functional (psychiatric) and organic (medical) causes of behavioral abnormalities may seem arbitrary. However, arranging the proper tests, treatments, consultants, and site of care depends on accurately making this differentiation. Several studies have documented high rates of patients receiving treatment for psychiatric illnesses that were really caused by treatable but undetected medical illness (2,3). In addition, patients with functional psychiatric syndromes such as schizophrenia often have comorbidities that go undetected or undertreated, leading to excess mortality (4).

CLINICAL PRESENTATION

The term *organic brain syndrome* (OBS) covers a range of clinical manifestations. The first two, delirium and dementia, are always presumed to be due to organic causes. Specific changes in cognitive function can help distinguish between delirium and dementia (5) (Table 152.1).

TABLE 152.1
Diagnostic Criteria for Delirium and Dementia[a]

Delirium

Definition: Disturbance of consciousness accompanied by change in cognition; not due to a pre-existing dementia

- Disturbance of consciousness:
  - Alterations in or lack of awareness of the environment
  - Reduced ability to concentrate
  - Attention: Inability to focus, sustain, or shift attention
- At least two cognitive deficits:
  - Memory deficit
  - Disorientation
  - Language disturbance
  - Perception alteration (i.e., hallucination or illusions)
- Rapid, abrupt onset over hours or days
- Organic cause:
  - Clinical evidence by history, physical, or testing, that the disturbance is due to the physiologic manifestations of a general medical condition or substance abuse or both

Dementia; often called neurocognitive disorders

Definition: Multiple cognitive deficits (especially memory) that are not due to a delirium. Consciousness is not necessarily clouded.

- Memory impairment:
  - Impaired ability to learn new information
  - Impaired ability to recall previously learned information
- At least one cognitive deficit:
  - Aphasia (language disturbance)
  - Apraxia (decreased ability to carry out motor activities despite intact motor function)
  - Agnosia (not recognizing or identifying objects despite intact sensory function)
  - Disturbed executive function (planning, organizing, sequencing, abstracting)
  - Intellectual impairments interfere with normal social or occupational function
- Organic cause:
  - The defects are caused by an underlying medical condition
  - The specific causes are important as some are correctable and some are not

[a]References 5, 6, 11, 12.

Delirium is often due to a life-threatening illness (5–10). In the elderly, it may be one of the most common disease presentations and is associated with high mortality rates (8,9,11). Delirium is defined

first by disturbed consciousness. Patients have altered awareness of the environment; difficulty in focusing, sustaining, or shifting their attention; and reduced ability to concentrate (6). Delirious patients may be hyperalert and have inappropriately fearful responses to normal stimuli. They may be hallucinating, hyperactive, or combative. There are also disturbances in at least two of the following: Perception, language, sleep cycles, memory, or psychomotor activity (6). However, the patient's limited awareness and inability to concentrate often make testing of these functions impossible (10). Delirium is also likely to resolve when the patient recovers from the underlying cause (5,11).

Dementia is now often referred to as a spectrum called neurocognitive disorders (6). It refers to the more gradual development of intellectual impairment sufficient to interfere with social and physical functioning (5,10). The hallmark finding is progressive impairment of memory. Memory deficits can be remarkable in patients who appear to function well otherwise. The diagnosis requires one additional cognitive impairment, such as loss of language, visual–spatial, or abstraction ability; impaired judgment; personality change; or reduced organizational ability (6). In contrast to delirium, consciousness is not clouded and deficits develop slowly over a more prolonged time course (5,10). The maintenance of normal consciousness and self-awareness and the slow progression can result in severe loss of function before family or providers detect the problem. In fact, it is frequently an acute precipitant such as medical illness or a change in living situation that calls attention to the long-term decline.

In addition to delirium and dementia or neurocognitive disorders, all of the major psychiatric diagnostic groups can be closely mimicked by the effects of medications or medical illnesses (7,12). Medical illness can cause clinical manifestations similar to those of psychosis, mania, depression, anxiety disorders, or even personality disorder. In some cases, a neuropsychiatric manifestation is the first symptom prompting treatment (12,13). Finally, medical illness can cause an acute worsening of behavioral symptoms in patients with

chronic existing psychiatric diseases that were previously well controlled (14).

DIFFERENTIAL DIAGNOSIS

The first challenge is to distinguish between functional psychiatric illness and OBS (7). One of the most important features in OBS is cognitive dysfunction (7,16). This may be undetectable unless actively sought (17). Most patients with functional disorders, even schizophrenic patients, have normal vital signs, motor and speech function, cognitive function, and memory (12). Thus, abnormalities in these areas cannot be assumed to reflect chronic psychiatric illness. OBS can also be distinguished from functional disorders by comparing the patient's syndrome to the standard psychiatric definitions (6). The presence of atypical features point to an organic cause (12).

It is useful to note similarities among delirium, dementia, and the more standard psychiatric diagnoses. Delirium shares features with anxiety disorder, acute psychosis, or mania (5,18). Alcohol withdrawal is a form of delirium (19). Dementia can appear similar to depression, chronic schizophrenia, or personality disorder. This same overlap in cause can assist in working through the differential diagnosis.

Many medical problems can result in compromised mental functioning and what appear to be manifestations of psychiatric disease (2,7,15,18). Table 152.2 lists the most common causes by clinical syndrome. Medications are by far the most common (7). The major life-threatening causes can be summarized as any profound disruption in blood or nutrient supply to the brain: Shock; hypoxia; sepsis; anemia; hypoglycemia; hypertensive encephalopathy; hyperthermia; fluid, electrolyte, or acid–base imbalance; carbon monoxide; intracranial infection or mass; or stroke (2,7,18). Alcohol withdrawal and Wernicke encephalopathy require emergent recognition and treatment. Infections, both neurologic and systemic, are important causes of OBS. Some infections such as viral encephalitis are seasonal (20,21). Metabolic derangements with behavioral symptoms are common in liver, renal, pulmonary,

thyroid, pituitary, and adrenal diseases (2,7,21). Trauma, illicit drugs, and toxins are common in the young (3,22). Patients with HIV infection may present with symptoms of secondary HIV mania as a first sign, and they are also more susceptible to CNS infections (13,23). Altered behavior in patients with cancer, heart disease, collagen vascular disease, or HIV infection should also prompt consideration of organic causes.

TABLE 152.2
Causes of Organic Brain Syndrome by Manifestation[a]

Organic Brain Syndrome	Causes
Delirium	
Emergency causes	Shock from any cause
	Hypoxia from any cause
	Hypoglycemia/electrolyte/acid–base imbalance
	Acute thiamine deficiency (Wernicke)
	Hyperthermia
	Thyroid storm
	Intracranial catastrophe: mass, blood, trauma, abscess, ischemia
	Carbon monoxide poisoning
	Alcohol withdrawal
	Toxic alcohols
Medications, toxins	Any drug with anticholinergic properties
	Clonidine
	Lidocaine
	Antabuse
	Caffeine/ergot
	Illicit drug intoxication
Neurologic	Subarachnoid hemorrhage
	Status seizure (petit mal, complex partial)
	Postictal syndrome
	Hypertensive encephalopathy
	Cerebral vasculitis: systemic lupus erythematosus, etc.
Endocrine	Diabetes mellitus
	Hyperthyroidism
	Addison disease
	Cushing disease (exogenous)
Metabolic, dietary	Hepatic encephalopathy
	Renal failure
	Hypomagnesemia
Infectious	Encephalitis/meningitis/brain abscess
	Sepsis
	Infective endocarditis
	Pneumonia
	Neurosyphilis
	Tuberculosis
	Typhoid fever/rheumatic fever
Miscellaneous	Alcohol or drug withdrawal syndromes
	Congestive heart failure
	Femur fractures (especially postoperative)
	Air and fat emboli syndromes
Dementia; Neurocognitive Disorders	
Medications, toxins	Beta-blockers
	Any drug with anticholinergic properties
	Methyldopa
	Clonidine
	Sedatives
Neurologic	Intracranial mass, blood, trauma, abscess
	Stroke, TIA
	Multi-infarct dementia
	Normal pressure hydrocephalus
	Chronic subdural hematoma
Endocrine	Diabetes mellitus
	Addison disease
	Cushing disease (endogenous)
	Hyperparathyroidism
	Apathetic hyperthyroidism
Metabolic, dietary	Vitamin B_{12} deficiency
	Chronic liver disease
	Hypercalcemia
	Chronic electrolyte imbalance
	Pernicious anemia
	Uremia
	Chronic thiamine deficiency (Korsakoff, beriberi)
Infectious	Neurosyphilis
	Tuberculosis (meningitis, miliary)
	HIV/AIDS
Miscellaneous	Chronic anemia
	Hypoxia
	Hypercarbia
	Depression (functional)
Anxiety Disorders	
Medications, toxins	Any drug with anticholinergic properties
	Bronchodilators
	Decongestants
	Diet pills and stimulants
	Digitalis toxicity
	Illicit drug intoxication
	Hallucinogens
	Hypotensive agents
Neurologic	Intracranial mass, blood, trauma, abscess
	Stroke, TIA
	Seizure disorder
	Essential tremor
	Postconcussion syndrome
	Cerebral vasculitis: systemic lupus erythematosus, etc.
Endocrine	Hypoglycemia
	Cushing disease
	Hyperthyroidism
	Menopause
Metabolic, dietary	Hyperkalemia
	Hypocalcemia
	Hyponatremia
	Hyperthermia
	Vitamin B_{12} or folate deficiency
	Secreting tumors (i.e., carcinoid, insulinoma, pheochromocytoma)
	Porphyria
	Caffeine
	Monosodium glutamate
Infectious	Encephalitis, meningitis
	Sepsis
	Pneumonia

Table continued on following page

Organic Brain Syndrome	Causes
Miscellaneous	Any hypoxia
	Hypovolemia
	Anemia
	Thrombotic thrombocytopenic purpura
	Hemolytic–uremic syndrome
	Myocardial infarction/arrhythmias/valvular disease
	Congestive heart failure/pulmonary edema
	Hypertension
	Anaphylaxis
	Asthma/chronic obstructive pulmonary disease
	Pneumothorax
	Pulmonary embolism
	Alcohol or drug withdrawal
	SSRI discontinuation syndrome
	Envenomation
Mania	
Medications, toxins	Corticosteroids
	Isoniazid
	H_2 blockers
	Cyclosporine
	Procyclidine
	Phencyclidine
	Cyclobenzaprine
	Bromides
	Levodopa
	Captopril
	Cocaine, amphetamines
	Nicotine
Neurologic	Intracranial mass, blood, trauma, abscess
	Stroke, TIA
	Temporal lobe seizure
	Multiple sclerosis
	Wilson disease
Endocrine	Huntington disease
	Hyperthyroid
	Cushing disease (exogenous)
	Addison disease
	Hepatic encephalopathy (early)
	Hemodialysis
Infectious	Caffeine
	Encephalitis, meningitis
	Sepsis
	Neurosyphilis
	HIV/AIDS
Miscellaneous	Influenza
	Alcohol or drug withdrawal
	SSRI discontinuation syndrome
Psychosis	
Medications, toxins	Any drug with anticholinergic properties
	Corticosteroids
	Histamine blockers
	Dilantin
	Alprazolam
	Stimulants, diet pills
	Isoniazid
	Antihypertensives
	Illicit drug intoxication
Neurologic	Intracranial mass, blood, trauma, abscess
	Stroke, TIA
	Cerebritis: systemic lupus erythematosus, etc.
	Complex partial seizure
Endocrine	Diabetes mellitus
	Hyperthyroidism
	Cushing disease (exogenous)
	Addison disease
Metabolic, dietary	Hypercalcemia
	Hypomagnesemia
	Hypoglycemia
	B_{12} deficiency
	Thiamine deficiency (Wernicke and Korsakoff)
Infectious	Acute hepatic encephalopathy
	Encephalitis, meningitis
	Neurosyphilis
	HIV/AIDS
Depression	
Medications, toxins	Beta-blockers
	Oral contraceptives
	Steroids
	Neuroleptics
	Ranitidine
	Anticholinesterases
	Benzodiazepines
	Alpha methyldopa
Neurologic	Frontal brain mass
	Stroke
	Multiple sclerosis
	Early dementia
	Epilepsy
	Tumors: pancreas, lung, prostate, brain
Endocrine	Diabetes mellitus
	Hypothyroidism, apathetic hyperthyroidism
	Addison disease
	Cushing disease (endogenous)
	Hyperparathyroidism
Metabolic, dietary	Hyponatremia
	Hypokalemia
	Hypocalcemia
	B_{12} deficiency
	Folate deficiency
	Chronic hepatic encephalopathy
	Uremia
Infectious	Neurosyphilis
	Mononucleosis
	Hepatitis
Miscellaneous	Influenza
	SSRI discontinuation syndrome

ED EVALUATION

Any patient with neuropsychiatric symptoms should receive a thorough history, physical and mental status examination (3,16,17).

Often, the history must be obtained from family or paramedics. Sometimes family members can articulate only that the patient has changed or worsened in some indefinite way. A frequent complaint in the elderly is a sudden refusal or inability to eat (1). The history should include information on medications, alcohol and drug use (including over-the-counter and herbal preparations), recent hospitalizations, surgeries, or trauma (5,12,19,24,25). Past psychiatric, endocrine, pulmonary, cardiac, renal, hepatic, malignant, and collagen vascular diseases and potential exposure to medications or toxins and risk factors for HIV infection are important history questions (2,7,13,17,23,26). Complaints such as headache, focal neurologic deficits, abdominal pain, dyspnea, fever, incontinence, nonauditory hallucinations, weight loss, cough, vomiting, or diarrhea also point to organic causes (1).

The patient's normal level of functioning and the pattern and rate of behavioral change must be ascertained. A recent abrupt change in a previously normal patient or new additional psychiatric manifestations in patients with chronic illness, are key signs of organic cause (7,8,11,27). Visual hallucinations, distortions, or illusions are also important clues to an organic etiology (12). Beware of missing new delirium occurring in a patient with chronic dementia. For example, acute worsening of chronic dementia can occur with a new stroke, pneumonia, sepsis, myocardial infarction, new medications, or metabolic, endocrine, or rheumatologic derangements. Sometimes it is not clear what precipitated the ED visit of a patient with chronic dementia. Sensitive questioning can reveal that family members no longer feel able to safely care for the patient and desire help or even nursing home placement. In other cases, the patient has had a catastrophic anger reaction that the family did not mention because they did not recognize it as a classic manifestation of dementia.

Physical examination findings indicative of an organic cause include abnormal vital signs, diaphoresis, jaundice, or pallor. Any motor disturbance such as tremor or partial complex seizure activity should be noted (12); either increased or decreased psychomotor activity levels may be seen (15). Signs of thyroid or adrenal disease

should be sought. A complete neurologic examination, including gait and tests of cognitive function, is required (7,15,16). Certain findings on mental status examination indicate an organic cause for behavioral changes. A neat, well-groomed appearance in a patient who is now disorganized indicates a very abrupt onset (17). Altered awareness of the environment, anxiety, labile mood, or rapid changes in mental status are associated with OBS, as are language abnormalities, altered speech, or disordered visual–spatial abilities. The new onset of mania in a patient older than the age of 30, or psychosis in patients older than 40, is highly unusual and should prompt testing for organic causes.

When ordering tests to detect the cause of OBS, it helps to categorize those causes as medication-related, toxicologic, neurologic, endocrine, metabolic, dietary, infectious, hepatic, renal, cardiac, or pulmonary. The specific evaluation should be guided by findings in the history, physical, and mental status examinations (7). Glucose, electrolytes, complete blood count, and renal function tests should be obtained (12). Additional useful testing may include electrocardiography, liver and thyroid function tests, toxicology, and arterial blood gases for hypoxia, CO_2 retention, and carbon monoxide exposure. A chest x-ray, urinalysis, and blood and urine cultures should be done when infection is suspected. Most patients warrant computed tomography of the head and lumbar puncture with cerebrospinal fluid cultures, including tests for tuberculosis and viral encephalitis (12). In patients with dementia, additional testing for correctable causes should include vitamin B_{12}, folate, thyroid, and syphilis testing (28).

ED MANAGEMENT

ED management generally depends on the underlying cause of OBS. The physician's first task is to rapidly identify and treat life-threats and then to take action to prevent injury (e.g., from falling out of bed or wandering away). As unsuspected alcoholism is common and the diagnosis of Wernicke encephalopathy or withdrawal can be difficult, thiamine should be given empirically and the glucose level checked early and followed up as necessary (12). Unless it is obvious

that the patient is suffering from severe alcohol withdrawal, extra caution is appropriate when initiating sedatives for behavioral control, as another condition may be causing global brain dysfunction, and there may be increased sensitivity to sedatives (11,15). Frequent reassessment is especially critical in patients with delirium, as the underlying causes are so serious and the condition can deteriorate rapidly. One-to-one observation, sedatives, or even restraints, may be necessary to ensure the patient's safety during evaluation and treatment (9,11,15).

CRITICAL INTERVENTIONS

- Rapidly search for and treat life threatening conditions.
- Distinguish between functional psychiatric illness and organic disease.
- Search for new medical illness superimposed upon a chronic dementia that can cause an acute but reversible decline or change.

DISPOSITION

Nearly all patients suffering from acute OBS need to be hospitalized for continued diagnostic evaluation and treatment or for the assurance of their physical safety (5). An exception is the patient with chronic dementia who has not had an acute decline in function but who is brought to the ED for evaluation of a long-term problem. Any medical illness superimposed upon a chronic dementia can cause an acute but reversible decline, so those with chronic dementia and acute worsening need admission. Another exception is the patient who is suffering from recreational drug or alcohol intoxication that clears in the ED. If these patients are discharged, they must go home with responsible family or friends.

Families caring for patients with progressive dementia need to be warned about the dangers of driving, cooking, or starting fires and to know that patients can wander away or can occasionally exhibit catastrophic anger reactions if they are under stress. It helps families to understand that these reactions can be a normal consequence of

dementia. Good follow-up must be ensured. Social services will be helpful in arranging home nursing care.

Psychiatric consultation may assist in the assessment of competency when the patient's judgment is in question. Some patients may try to leave the hospital once they are admitted; a recorded psychiatric competence evaluation is extremely helpful to hospital staff (9,11). Patients with acute impairment of judgment or consciousness or with cognitive deficits do not have sufficient decision-making capacity to sign themselves out of the hospital against medical advice (30). There is growing use of empiric symptom severity scores, such as the Organic Brain Syndrome Score for assessing OBS, and there are inpatient intervention programs that show promise for improvement in diagnosis and management (9,11,25,27).

Common Pitfalls

- Failing to do a complete history, physical, and mental status examination in all patients with psychiatric symptoms (3,7,16).
- Failing to note abnormal vital signs as an indicator of possible organic causes.
- Assuming that apparent psychiatric symptoms are due to functional psychiatric disorders (3,7).
- Assuming that physical complaints in a psychiatric patient are due to functional causes (1).
- Failing to detect a mild early cognitive deficit or assuming that it is due to chronic functional illness.
- Missing acute delirium that occurs in a patient with chronic dementia.
- Becoming distracted by combative or abnormal behavior and thus failing to follow through in performing a complete evaluation and frequent reassessments.

CHAPTER 153 Headache

Benjamin W. Friedman

Head pain accounts for 2 million emergency department (ED) visits annually in the United States (1). The vast majority of headaches presenting to the ED do not threaten life or limb. Most often, they are acute manifestations of an episodic headache disorder or a self-limited, infectious or inflammatory condition readily amenable to treatment. Management of the patient with headache in the ED requires distinguishing the small fraction of patients with serious illness who require immediate diagnosis and hospitalization from the great majority in whom the clinical focus is directed toward headache-specific, short-term pain management, prophylaxis against recurrence, explanation, reassurance, and careful follow-up, while minimizing throughput time and use of healthcare resources.

CLASSIFICATION OF HEAD PAIN

The simplest means of categorizing headaches is to dichotomize into primary headaches (e.g., migraine) versus "organic" or secondary headaches. The latter are so named because they are secondary to some underlying cause (e.g., subarachnoid hemorrhage) (2).

The pain-sensitive structures of the head include the blood vessels and all extracranial structures of the head and neck. The only intracranial structures sensitive to pain are the vasculature of the brain, the dura mater, the venous sinuses, and cranial and cervical nerves. The parenchyma of the brain itself and much of its meningeal coverings are not pain sensitive.

For many years, traditional teaching held that there were three major mechanisms of head pain: Vasodilatation within the cranial

vasculature, causing a “vascular” headache; spasm of the neck and scalp muscles, causing a “muscle contraction” headache; and traction on blood vessels or inflammation around or within these and other pain-sensitive structures, causing a “traction–inflammatory” headache. More recently, traditional concepts of the etiology of headache, particularly of migraine, have given way to explanations based on animal models and neuroimaging in which abnormal release of vasoactive neuropeptides actuates nociceptive pathways. It is now clear that vasodilation is not the primary mechanism of headache. Headache is best thought of as a cranial and cervical neuropathy causing activation of secondary and tertiary nociceptive pathways within the brainstem (3).

For emergency clinicians, thorough headache management addresses the twin challenges of accurate diagnosis and effective treatment (Table 153.1). Secondary headaches, particularly malignant secondary headaches, must be considered and excluded. This often can be accomplished based on the description of the acute headache and the patient’s past headache history. For select patients, a diagnostic workup is indicated (Table 153.2). Patients with an acute exacerbation of a recurrent primary headache disorder should be treated with disease-specific therapies rather than nonspecific analgesics.

TABLE 153.1
Differential Diagnosis of Headache

Secondary Headache	Characteristic Features
Meningitis/encephalitis	Fever, altered mental status
Subarachnoid hemorrhage	Abrupt onset headache
Hypertension	Marked elevation in mean arterial pressure
Narrow-angle glaucoma	Steamy cornea, nonreactive pupil
Sinusitis	Symptoms of upper respiratory infection
Cervical artery dissection	Facial pain, Horner syndrome
Pituitary apoplexy	Bitemporal visual loss, hypotension
Cerebral venous thrombosis	Thromboembolic risk factors
Brain tumor	Not necessarily progressive and constant
Temporomandibular joint syndrome	Worsened by mastication; Tender TM joint
Low CSF pressure headache	Orthostatic
Idiopathic intracranial hypertension	Obese patients. Transient visual obscurations
Primary Headache	**Characteristic Features**
Migraine	Unilateral, throbbing, photo and phonosensitivity
Tension-type headache	Bilateral, pressure like, mild to moderate
Cluster headache	Severe, periorbital, lacrimation, rhinorrhea, conjunctival injection
Trigeminal neuralgia	Lancinating facial pain

TABLE 153.2
Ten Headaches to Worry About

1. Acute headache, characterized as "first or worst" of the patient's life
2. New-onset headache associated with fever and alteration in mental status
3. New-onset headache with vomiting unexplained by other systemic illness
4. Any headache associated with focal findings, including alterations in vision, unless focality is known to be chronic and unchanged from baseline
5. Headache associated with red eye
6. Any headache associated with papilledema
7. Single acute headache with pain on neck flexion but absent on rotation
8. Subacute headache, unremitting or progressively worsening
9. Acute or subacute headache in the elderly
10. Any headache in the immunocompromised host, especially if HIV-positive with low T cell count

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Secondary Headaches

Meningitis/Encephalitis

The headache of meningitis tends to be generalized, though it is the constellation of signs and symptoms rather than the headache itself that remains key to diagnosis (4). Alterations in mental status are typical for bacterial meningitis, as is fever. The absence of fever, neck stiffness, and altered mental status practically eliminates bacterial meningitis from the differential diagnosis, though the individual components of this triad have poor predictive ability (5). Classically, the headache of meningitis worsens with sharp, sudden head movements—so called jolt accentuation. Patients with encephalitis may present with isolated headache, but evidence of brain parenchymal involvement, such as altered mental status, seizures, or focal neurologic findings should be apparent. In the United States, patients with Lyme meningitis frequently recall the classic erythema migrans rash and often present with a concomitant seventh cranial nerve palsy, while in Europe, painful radiculopathy is more common (6). Opportunistic infections are discussed below.

Subarachnoid Hemorrhage

Headache of SAH is the prototypic “first or worst” headache of one’s life, of sudden onset, often associated with nausea, vomiting, neck stiffness, and a transient alteration of consciousness. In patients with focal findings or sustained abnormalities of consciousness, the need for a neuroimaging study is apparent. However, some patients present without focal neurologic findings. In these patients, SAH may be difficult to distinguish from a first attack of migraine.

An especially difficult challenge for the emergency physician is identification of the “sentinel leak” that precedes major hemorrhage in one-third of patients. Detection of this premonitory bleed presents an opportunity to prevent a neurologic catastrophe. Clinical decision rules may allow the clinician to risk stratify patients (7).

Hypertension

Elevated blood pressure and headache have long been linked in the public mind. The causative pathway remains uncertain. It is clear that both hypertension and headache may both be present in malignant processes such as preeclampsia, posterior reversible encephalopathy syndrome, and reversible cerebral vasoconstriction syndrome. However, most headaches in hypertensive patients are either migraine or tension type and are only rarely due to elevated blood pressure. Mild-to-moderate elevations in blood pressure are not generally believed to be a cause of headache. By in large, it is felt that only acute elevation of diastolic pressure of at least 25% above baseline or sustained diastolic elevations in excess of 130 mm Hg have the potential to cause headache (2).

Narrow-Angle Glaucoma

Ocular or periorbital pain characterizes headache caused by narrow-angle glaucoma. The diagnosis of acute glaucoma also requires diminished visual acuity, a pupil that is typically fixed in midposition, an edematous (“steamy”) cornea, perilimbal injection, and increased intraocular pressure. Vomiting may be the dominant feature, especially in the elderly, who may also present with altered mentation.

Sinusitis

Acute sinusitis presents with frontal headache or facial pain, tenderness, and fullness. The diagnosis of acute sinus headache requires symptoms of a recent or intercurrent upper respiratory infection. Specifically, patients should report rhinorrhea or nasal congestion, stuffiness or blockage, and fever. Chronic sinusitis does not cause acute headache. Migraine, too, may present with nasal congestion or rhinorrhea. Physicians should consider this latter diagnosis in all patients who presents with recurrent headaches (8).

Cervical Artery Dissection

Spontaneous dissection of the cervical arteries is an uncommon syndrome, often associated with surprisingly minor trauma. It is marked by sudden onset of headache associated with facial or neck pain and focal ischemic symptoms. The pain and its location are determined by the location of the dissection in the carotid or

vertebrobasilar system. In the carotid system, the pain is anterior and may be accompanied by monocular symptoms, Horner syndrome, and other focal findings. With dissection in the posterior circulation, the pain is occipital, and brainstem findings predominate.

Pituitary Apoplexy

Acute hemorrhage or infarction of the pituitary gland is a rare cause of sudden-onset headache that typically occurs in patients with underlying (although often not diagnosed) pituitary adenoma. This headache may be accompanied by decreased visual acuity, temporal visual field cuts, ocular palsies, and hormonal dysfunction such as acute adrenal crisis.

Cerebral Venous Thrombosis

Thrombosis of the venous system of the brain is an uncommon cause of headache that is often difficult to diagnose. The onset may be sudden or gradual. Both noncontrast head CT and spinal fluid analysis are often normal, so diagnosis is often delayed until after hospital admission. Magnetic resonance venography is useful in making the diagnosis. Risk factors include traditional thromboembolic risk factors, pregnancy and the postpartum period, trauma, and contiguous sources of infection.

Brain Tumor

Headache is the initial symptom of primary brain tumor in half of all cases, though by the time patients present to medical attention, they have often developed other signs suggestive of a malignant CNS process. Headache is an uncommon presenting symptom of a metastatic undiagnosed non-CNS malignancy. Brain tumor headache is nonspecific and cannot be used to differentiate brain tumor from benign headache etiologies. Initially brain tumor headache is often mild to moderate in intensity, relieved by over-the-counter analgesics, and diffuse. Brain tumor headache may be intermittent rather than progressive and while it may awaken the patient at night, worsen with Valsalva maneuver, or present with nausea and vomiting, it is often not associated with these signs of increased intracranial pressure (9).

Temporomandibular Joint Syndrome
Headache precipitated by chewing or jaw movements may be due to temporomandibular joint syndrome. Definitive diagnosis requires evidence of joint pathology on imaging studies, though may be suspected if physical examination reveals a tender joint (2).

Headache Associated with Low Cerebrospinal Fluid Pressure
Low cerebrospinal fluid pressure headaches occur most commonly in the setting of recent lumbar puncture or spinal anesthesia. Noniatrogenic causes of low CSF pressure headaches are increasingly recognized. Low CSF pressure headaches are characteristically orthostatic. There is worsening of pain, dizziness, and nausea when the patient is upright and improvement on lying down. Diplopia with cranial nerve palsies may be present. The history is often diagnostic. If an LP is performed, an opening CSF pressure of <30 mm H_2O strongly suggests this diagnosis.

Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)
Headache in idiopathic intracranial hypertension is associated with high CSF pressures in the absence of intracranial structural disease. This is characteristically a disease of young obese women. Because of overlapping demographics, idiopathic intracranial hypertension may be misdiagnosed as migraine. Pain is often postural and associated with pulsatile tinnitus, nausea, vomiting, and eventually progressive visual loss, which may occur rapidly. Patients may report transient visual obscurations. Papilledema is present in about 90% of patients. The diagnosis is confirmed by CSF pressures >250 mm H_2O and unremarkable neuroimaging (10).

Temporal (Giant Cell) Arteritis
Headache is the dominant complaint in temporal (giant cell) arteritis, a progressive, systemic, inflammatory disorder. The syndrome is exceedingly rare in patients younger than 50 years of age. It is accompanied by constitutional symptoms such as anorexia and weight loss. The onset is gradual, with polymyalgia, proximal weakness, masseter claudication, and periocular discomfort developing over months to years. The diagnosis is suggested by firm,

tender, temporal and occipital arteries and an elevated erythrocyte sedimentation rate (>50 mm/h), although about 25% of cases have only mild elevations of the sedimentation rate. Major complications include monocular blindness and stroke (11).

Headache in Immunocompromised HIV-Positive Patients

Headache in immunocompromised patients with HIV is often caused by a benign recurrent headache disorder. However, the clinician should consider infectious etiologies, particularly cryptococcal meningitis, which may present with no more than an indolent subacute headache that seems like a persistent tension-type headache. HIV itself may cause headache, particularly as T cell counts dwindle. The list of other opportunistic CNS infections includes mycobacteria (*Mycobacterium tuberculosis* and *Mycobacterium avium-intracellulare*), spirochetes (*Treponema pallidum*), viruses (herpes simplex, herpes zoster, cytomegalovirus, and JC virus), and protozoa (*Toxoplasma*). Noninfectious causes of headache include CNS lymphoma (primary and secondary) and adverse reaction to antiretroviral or prophylactic therapy (4).

Posttraumatic Headache

Posttraumatic headache begins within 1 week of traumatic brain injury. While if often resolves within several months, it will persist in a minority of patients as either a chronic or episodic headache. Headache is often part of a postconcussive syndrome that may include dizziness, neurocognitive impairment, depression, irritability, and emotional lability. Phenotypically, it may take the form of migraine, tension type, or cervicogenic headache. Prognosis is varied and not related to initial mechanism or severity of injury. History of pre-existing headache disorder, and psychiatric and social stressors will impact outcome (12).

Headache in Pregnancy

In general, pregnancy decreases the frequency of migraine attacks in patients with a history of migraine. This becomes more apparent in the latter two trimesters. Benign causes of headache predominate by far among women who complain of headache in pregnancy. Headache may be the presenting symptom of preeclampsia or

eclampsia. These headaches have a vascular throbbing quality. An assessment of blood pressure, proteinuria, and reflexes should occur in all patients with headache in the final trimester of pregnancy. In addition, the latter half of pregnancy and the first several weeks postpartum are considered a thrombophilic period. Clinicians should consider the diagnosis of venous sinus thrombosis for de novo headaches that present in this time period.

Acute Headache Associated with Metabolic Disorders

Of all patients presenting to the ED with headache, a little more than one-third have a systemic infection, usually associated with fever, causing their head pain. Other metabolic causes of headache include hypoglycemia, hypoxia, carbon monoxide poisoning, and hypercarbia.

Primary Headache Disorders

The two most common causes of headache visit in emergency practice are the highly prevalent primary headache disorders: Migraine and tension-type headache. The acute migraine or tension-type headache that causes the patient to visit the ED is a symptom of an underlying episodic headache disorder, which ultimately requires attentive long-term management. For these headaches a diagnostic workup is generally not needed. The goal of the emergency clinician is to reassure the patient of the benign nature of the headache, provide durable short-term relief, and assist the patient to access continuing headache care.

Migraine

Migraine affects 12% of the US population with a 3:1 female predominance. If left untreated, an acute migraine attack generally lasts between 4 and 72 hours (2). Classically described features include unilateral location, pulsating quality, moderate or severe intensity, aggravation by routine physical activity, and association with nausea, photophobia, and phonophobia, although not all of these features are required for diagnosis. Constitutional symptoms occur primarily during the prodrome and the “postdrome.” These include mood changes, fatigue, myalgias, food cravings, and

irritability. Neurologic symptoms occur mainly during the migraine aura (which occurs in a minority of patients) and include visual phenomena such as bright sparkling lights (scintillating scotomata), jagged lines (fortification spectra), and geometric figures. A unique characteristic of migraine visual auras is their propensity to move across the visual field and to vary in color or intensity, sometimes shifting from positive to negative phenomena (scotomata). Less common migraine auras include motor abnormalities (hemiparesis, ophthalmoplegia, aphasia), sensory dysesthesias, and brainstem disturbances (vertigo, ataxia).

Cluster Headache

In contrast to migraine, cluster headache is uncommon, affecting 0.1% of the population. Prevalence is three to four times higher in men than woman and associated with tobacco use. The first episode of cluster headache may be indistinguishable from SAH, carotid artery dissection, or acute orbital, periorbital, or ocular disease. Unilateral pain is localized to the orbital, supraorbital, and/or temporal areas. Attacks are associated with one or more of the following ipsilateral signs: Conjunctival injection, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and eyelid edema. Restlessness and agitation are common features. Attacks characteristically occur in clusters lasting for weeks or months, with multiple extremely painful attacks occurring several times each day (13).

Tension-Type Headache

Tension-type headache is the most common type of primary headache, with a prevalence in the general population of nearly 40% (14). The pain is typically bilateral, pressing or tightening in quality, of mild-to-moderate intensity, and does not worsen with routine physical activity. There is no nausea, but photophobia or phonophobia may be present. Tenderness of the pericranial musculature may accompany this headache (2).

Trigeminal Neuralgia

Trigeminal neuralgia is the prototypic form of facial neuralgia, characterized by repetitive, unilateral, lancinating pain in the distribution of at least one branch of the trigeminal nerve. Attacks may be triggered by some minor stimulus, such as a light touch on the face. Sensory deficits and bilateral symptoms are suggestive of a specific underlying anatomic lesion (2).

Coital Headache

Headache that occurs immediately before, during, or shortly after orgasm is termed *coital* or *orgasmic headache.* The pain is often severe and may persist for several hours. If there is no prior history of coital headache, SAH must be excluded. Reversible cerebral vasoconstriction syndrome can cause recurrent coital headaches.

Chronic Headache

Patients presenting to the ED with chronic headache (i.e., headache that has been present for months to years) are part of what has been called the "last straw" syndrome (15). Chronic headaches can be divided clinically into several different groups, each requiring a different diagnostic and therapeutic strategy. These include patients with features of chronic tension-type headache, chronic migraine (most often transformed from an episodic pattern to a chronic daily pattern), and, rarely, tumor, subdural hematoma, idiopathic intracranial hypertension, and posttraumatic headache. A comorbid association exists between headache and psychiatric disorders including depression, and anxiety disorder, but current opinion does not favor a causal relationship. Some patients with severe tension-type headache or frequent migraines overuse nonnarcotic analgesics resulting in worsening of the frequency of the underlying headache attacks.

ED EVALUATION

A meticulous history is the key to headache diagnosis. Only in unusual circumstances does the neurologic examination, laboratory

testing, or neuroimaging reveal an abnormality that was completely unsuspected after a careful history.

Headache History

Temporal Profile

Headaches should be classified into one of the following four categories.

1. Single acute: Is this a “first/worst” headache of sudden onset?
2. Recurrent acute: What are the frequency, pattern, and duration of individual headache episodes?
3. Subacute: Is the headache progressively worsening?
4. Chronic: Has there been a pattern break or is this a “last straw” visit to the ED?

Associated Symptoms

In particular, look for transient loss of consciousness at onset, nausea, vomiting, neck stiffness, unilateral lacrimation or rhinorrhea, photophobia, phonophobia, or visual changes.

Circumstances of Onset

For single acute headaches, determine exactly what the patient was doing when the headache began. For recurrent headache, identify typical precipitants.

Prodromes and Aura

Prodromes such as a shift in appetite, mood, sleep patterns, or energy level, may precede the headache by several days and suggest migraine. Visual or sensory aura, which precede the headache by no more than 1 hour and generally resolve with headache onset, defines the subtype of migraine with aura.

Location of Pain

Hemicranial, hemifacial, and unilateral ocular and periorbital pain have greater discriminating value than holocranial or bilateral pain.

Quality and Severity of Pain

Quality and severity of pain have limited value in identifying the type of headache and correlate poorly with the seriousness of

underlying disease.

Age at Onset
For many patients, migraine begins in the second decade of life, with a peak prevalence in the fourth decade of life. New-onset headache in the elderly is worrisome and deserves a thorough evaluation.

Recent Trauma
Recent history of trauma is relevant to chronic subdural hematomas and posttraumatic headaches.

Relief Measures
Headaches that are substantially relieved by lying down are usually posttraumatic or low CSF pressure headaches. Patients with migraine seek dark, quiet spaces, while those with cluster prefer to pace.

Family History
Migraine, and to a lesser extent, a predisposition to SAH are inherited.

Medical History
Ask about concurrent illnesses, medications (including oral contraceptives), hospitalizations, allergies, smoking, alcohol, drug use, and risk factors for HIV.

Occupational History
Note exposure to carbon monoxide, fumes, solvents, and other toxins.

Psychosocial History
Search especially for signs and symptoms of depression, anxiety, and stress.

Multiplicity
Many patients suffer from different kinds of headaches. To minimize confusion, it is important to determine this early and to obtain parallel but distinct histories of each headache type.

Physical Examination

General Examination

After obtaining vital signs, the remainder of the nonneurologic examination should be goal directed, including the eyes, neck, face, and scalp. Visual acuity should be checked, visual fields assessed, and the eye examined for ptosis, conjunctival injection (perilimbal vs. diffuse), corneal clouding, and pupillary size, reactivity, and equality. Any suggestion of acute glaucoma mandates measurement of intraocular pressure.

A funduscopic examination may identify signs of increased ICP. Spontaneous venous pulsations (SVPs) are lost when the ICP exceeds about 250 mm H_2O, though absence of SVPs in patients with normal ICP occurs in about 20% of the normal population. Bilateral papilledema is a highly specific indicator of increased ICP but may lag behind acute elevations of ICP by as much as 1 week (10).

The neck should be examined for pain with flexion, which indicates meningeal irritation secondary to chemical or infectious meningitis. Tension-type headache may produce tightness in the paracervical muscles with discomfort on flexion. Unlike the nuchal rigidity of meningitis, tension-type headache causes pain with chin-to-shoulder rotation of the head. Because it may take several hours for subarachnoid blood to reach the cervical area of the meninges and several more hours for it to produce a chemical meningitis, absence of nuchal rigidity early in the course of an SAH does not reliably exclude this entity. Tender areas along the spine may indicate a cervical etiology of headache.

The sinuses, temporomandibular joints, and scalp should be palpated for tenderness, paying special attention to the temporal and occipital arteries in older patients. In posttraumatic headache, hemotympanum, CSF otorrhea, infraorbital ecchymoses, posterior auricular ecchymoses, and CSF rhinorrhea indicate basilar skull fracture.

Neurologic Examination

Mental status assessment is a critically important feature of the neurologic examination that is commonly overlooked. Focality is detected most readily by pronator drift, asymmetry of cranial nerves II to VIII, and abnormalities of gait and station. In general, sensory

examination (other than cranial nerve V), assessment of reflexes, and motor testing of individual muscle groups are not efficient use of the emergency physician's time in the evaluation of the patient with headache.

Laboratory Testing

As with the physical examination, laboratory tests are usually normal. In patients with a history strongly suggestive of a particular kind of headache (e.g., migraine), no laboratory tests are necessary. An exception to this rule is the erythrocyte sedimentation rate and C-reactive protein in patients suspected of having temporal arteritis (16). In certain situations, an assessment of carboxyhemoglobin level will indicate the diagnosis.

Imaging

When a diagnosis can be made on the basis of the history and a normal clinical examination, no imaging is needed. Patients with new-onset headache often require CT or magnetic resonance imaging at the time of their ED visit. Those with subacute and chronic headache may have an imaging procedure scheduled electively.

Optimal imaging modality depends on availability. For most patients at most EDs, a noncontrast head CT can be obtained in an expedited manner, and provides valuable information about space-occupying lesions and acute bleeds. MRI is less readily available on an emergent basis, but is generally more sensitive than CT, and does not expose patients to ionizing radiation. A noncontrast head CT is the preferred test for evaluation of acute SAH, as small amounts of acute blood are more difficult to detect on the MRI. Detection of subarachnoid hemorrhage on CT is dependent on the amount of subarachnoid blood, resolution of the scanner, and skill of the interpreter and is inversely related to time interval from onset of bleeding to scan. Sensitivity of noncontrast head CT for subarachnoid blood approaches 100% if performed within 6 hours of headache onset and greater than 90% if performed with 24 hours (17). Noncontrast head CT is inadequately sensitive for subarachnoid blood beyond 24 hours.

The sensitivity of MRI is inferior to that of CT during the first 24 hours after an SAH, and improves thereafter. In addition to late identification of SAH, MRI is preferred for imaging the posterior fossa (cerebellum and brainstem), and detecting nonhemorrhagic stroke.

Digital subtraction angiography is the traditional gold standard for evaluation of aneurysms and arteriovenous malformations causing subarachnoid hemorrhage. CT angiography (CTA) can be performed rapidly, has a sensitivity of approximately 95% for the detection of aneurysms, and is playing an increasing role in the diagnostic evaluation of patients with subarachnoid hemorrhage (18). MRA has performance characteristics similar to CTA but may be less available and less feasible depending on patient condition.

Lumbar Puncture

There are two primary indications for an emergency LP in a patient with headache: Suspicion of CNS infection or substantial suspicion of subarachnoid hemorrhage. The other circumstance in which an LP is the diagnostic standard is in idiopathic intracranial hypertension.

The risk of herniation after LP in patients with increased ICP or a mass lesion is low but has not been precisely quantified. A subset of young, healthy, neurologically intact ED patients can safely undergo LP without screening CT (19). Postural headache is a common occurrence after diagnostic LP. Despite common teaching, no evidence exists from randomized trials to suggest bed rest is more effective than immediate mobilization after LP. The role of fluid supplementation in the prevention of postural puncture headache remains uncertain. Several meta-analyses have found the use of smaller diameter and atraumatic-tip needles to be associated with a lower incidence of postural puncture headache than larger and bevel-tip needles, respectively. If a beveled needle is used, the bevel should be aligned parallel to the dural fibers (i.e., pointed toward the patient's hip) (20).

KEY TESTING

- Only a minority of ED patients with headache require diagnostic evaluation. For the emergency clinician, deciding whether or not to test is equally important as deciding which test to order.
- Laboratory values, while suggestive, are rarely helpful. The exception to this is an erythrocyte sedimentation rate and C-reactive protein. When these values are normal, the diagnosis of temporal arteritis is practically excluded.
- Neuroimaging is useful to exclude disease in a minority of patients. Benefits of CT scan such as availability, rapidity of test, and sensitivity for acute blood must be weighed against risk of radiation sequelae. Benefits of MRI such as increased sensitivity for space-occupying lesions, demyelinating processes, and ischemia must be weighed against considerations such as throughput time and costs to the healthcare system.

ED MANAGEMENT AND DISPOSITION

Treatment of many of the secondary headaches mentioned above is discussed in corresponding chapters elsewhere in this text. Below, we review management and disposition of the primary headaches and select secondary headaches not discussed elsewhere.

Migraine

Table 153.3 lists parenteral therapies for acute migraine (21). Historically, emergency clinicians used opioids to treat acute migraine. A growing consensus favors the use of the disease-specific agents discussed below, rather than nonspecific analgesics, with the goals of decreasing ED recidivism, improving functionality after treatment, and preventing progression of the underlying episodic migraine disorder to a chronic persistent illness (22).

TABLE 153.3
Parenteral Therapies for Acute Migraine

Drug	Dose	Route	Repeat Dose	Comments
NSAID				
Ketorolac (Toradol)	60 mg 30 mg	IM IV	6 h	Reasonable therapy, especially for headaches without migraine or cluster features. Not as effective for migraine as DHE, antiemetic dopamine antagonists or sumatriptan
Serotonin Agonists				
Dihydroergotamine	0.5–1 mg	IM, SC or IV over 30–60 min	0.5–1 mg IM, SC or IV over 30–60 min	Less effective than sumatriptan and dopamine antagonists but less relapse than sumatriptan. Combine with antiemetic (e.g., metoclopramide or prochlorperazine) for added efficacy and tolerability. Contraindicated in cardiovascular disease and pregnancy; d/c if chest pain, worsening headache or increased blood pressure.
Sumatriptan (Imitrex)	6 mg	SC	6 mg SC in 1 h (max 12 mg per 24 h)	More rapid action than DHE; 50% rebound within 24 h; higher cost, poorly tolerated by some patients and contraindicated in those with cardiovascular risk factors
Dopamine Antagonists				
Prochlorperazine (Compazine)	10–20 mg	Slow IV infusion	10–20 mg in 1 h	May cause dystonia, akathisia (consider administration with diphenhydramine 25–50 mg IV); PR less effective than IV
Metoclopramide (Reglan)	10–20 mg	IV in 50 mL D5W over 20 min	40 mg in 1 h	Enhances gastric emptying; may cause dystonia, akathisia (consider administration with diphenhydramine 25–50 mg IV)
Droperidol	1.25–2.5 mg	Slow IV infusion	Repeat dose ok	Black box warning for QT prolongation. May cause akathisia.
Corticosteroids				
Dexamethasone	10–20 mg	IV	60 mg prednisone tapering 5 mg/d	May decrease inflammation; interval medication until prophylactic agents take effect Increasing evidence for dexamethasone as primary therapy to decrease recurrence of headache after ED discharge
Opioids				
Morphine	0.1–0.15 mg/kg	IV	Titrate against pain prn	Most of above regimens provide superior pain relief in controlled trials
Hydromorphone	1–2 mg	IV		Generally considered therapeutic option of last resort

The established efficacy and selective pharmacology of the triptans have earned this group of drugs a central role in the abortive management of migraine over the past decade. Subcutaneous sumatriptan, the putative gold standard, is highly effective if administered early after headache onset. This medication is best avoided in patients with cardiovascular risk factors and those who are pregnant. Unpleasant adverse events such as palpitations and flushing frequently accompany this medication, and headache recurrence after ED discharge occurs in nearly two-third of patients who initially experience relief. This medication should be reserved for those who have had a previous favorable experience with it.

Newer triptans offer additional dosage forms and longer half-lives, though to date, sumatriptan is the only parenteral option. ED use of oral triptans may be limited by nausea, vomiting, and delayed gastrointestinal absorption, a frequent feature of migraine attacks.

Dihydroergotamine, a more tolerable form of the original ergot alkaloid, is best administered as a slow intravenous drip following pretreatment with an antiemetic, preferably one of the antiemetics with antimigraine properties discussed below. Dihydroergotamine

should not be used in those with cardiovascular risk factors, those who are pregnant, or taking macrolide antibiotics or antiretrovirals.

The intravenous dopamine antagonists metoclopramide, droperidol, and prochlorperazine can be used as monotherapy or as adjunctive therapy in combination with other abortive agents (21). The efficacy of these agents has been established in multiple systematic reviews (21) though the therapeutic mechanism of action is not well understood. The dopamine antagonists are well tolerated and highly effective with few practical contraindications. Akathisia, which may at times be severe enough to interfere with the therapeutic plan, can be mitigated with the coadministration of 25 to 50 mg of intravenous diphenhydramine.

Parenteral nonsteroidal anti-inflammatory drugs or salicylates may be used as primary or adjunctive therapy for acute migraine. Caution should be exercised in patients who have taken substantial doses of over-the-counter medication prior to ED presentation, which is not uncommon.

Corticosteroids such as dexamethasone decrease the frequency of headache recurrence after ED discharge, though with a number-needed-to-treat of 10, this class of medication may not be appropriate for every patient (21). Unfortunately, there is no evidence to guide optimal dosage and duration of therapy with corticosteroids. There is a belief that patients who present with status migrainosus (unremitting migraine for greater than 72 hours) are best served by a course of corticosteroids lasting at least several days.

Cluster

High-flow 100% oxygen is highly effective for cluster headache and should be administered as soon as the patient with cluster headache enters the ED (13). Dihydroergotamine (DHE) and sumatriptan are also effective in the ED management of cluster. However, concerns about coronary vasospasm limit the use of these drugs in patients with any cardiovascular risk factors. Limited evidence suggests the dopamine antagonists may be effective as well. On discharge, patients with an exacerbation of cluster should receive verapamil, starting at 80 mg tid, if there are no contraindications. A tapering

course of steroids should be prescribed, and close follow-up arranged (13).

Tension-Type Headache

Many patients with tension-type headache can be managed with oral analgesics, such as nonsteroidal medication, aspirin, or acetaminophen. Those who require parenteral medication will often respond to migraine medications. The parenteral dopamine antagonists are highly effective for tension-type headache. Subcutaneous sumatriptan should be reserved for those patients with tension-type headache who have previously experienced migraine headache.

Trigeminal Neuralgia

Trigeminal neuralgia syndrome responds best to carbamazepine, which has a number-needed-to-treat of less than two (23). Oxcarbazepine or baclofen may be used as second-line agents. Nonsteroidals or opioids may be necessary until other medications take effect. Facial nerve blocks with long-acting local anesthetics will provide immediate but short-lived relief in selected patients. All patients should be referred to specialty care for a diagnostic workup, which may reveal an anatomic cause such as multiple sclerosis, tumor, or neurovascular compression.

Coital Headache

Once subarachnoid hemorrhage has been excluded, coital headache patients require explanation, reassurance, and referral. It is reasonable to offer the patient a therapeutic trial of indomethacin 50 mg PO, taken 1 hour before intercourse.

Posttraumatic Headache

Once the diagnosis has been confirmed by a normal CT or MRI, posttraumatic headache patients should be educated and reassured. Confirmation that this is indeed “real” and that it will improve with

time is an important therapeutic intervention. Patients should be referred to a neurologist.

Headache Associated with Low Cerebrospinal Fluid Pressure

Traditional management of post-LP headache includes fluid replacement and bed rest. Other treatments include administration of intravenous caffeine and performance of an epidural blood patch, although a solid evidence base for these practices is lacking (24). Unless individuals are incapacitated by the headache, they can generally be managed as outpatients.

Idiopathic Intracranial Hypertension

Acute symptoms can be relieved with lumbar puncture, with the goal of removing enough CSF to normalize pressure. Acute headache may be relieved with migraine medication. Control of pain does not treat the underlying threat to the patient's vision. Patient should be prescribed acetazolamide and referred for specialty care. Modest reduction in weight may improve prognosis. If acuity worsens in spite of maximal medical management, an optic sheath decompression or ventricular shunt will be needed (10).

Temporal Arteritis

An erythrocyte sedimentation rate and C-reactive protein should be used to exclude temporal arteritis in patients older than 50 who present with new-onset headache. Because untreated patients are at risk of blindness, all patients with the working diagnosis of temporal arteritis should immediately receive corticosteroids and be referred for temporal artery biopsy.

Headache in Immunocompromised HIV Patients

Immunocompromised HIV-positive patients presenting with headache are at high risk for opportunistic infections. Emergency clinicians should have a low threshold for initiating a diagnostic

workup, including neuroimaging to look for mass lesions, lumbar puncture to evaluate for meningitis, and a serum cryptococcal antigen, which is highly sensitive for cryptococcal meningitis (4).

Chronic Headache

Individuals with chronic headache are among the most challenging to manage in a busy ED because their underlying pain disorder cannot be solved from the acute setting. Though tempting to treat the acute pain with parenteral opioids, this course of action will not improve the patient's long-term course. Within the heterogeneous group of patients with chronic headache, one must try to identify treatable subsets, such as those with medication overuse headache and untreated psychiatric comorbidities, and make the appropriate referrals. Comprehensive headache management programs with a multidisciplinary approach and individualized treatment plan have demonstrated some benefit in a select group of frequent ED users with chronic headache who are motivated to attend specialized headache classes (25). In general, patients with chronic headache, including chronic tension-type headache, chronic migraine, and medication overuse headache can benefit most from the expertise of a headache or pain specialist.

CRITICAL INTERVENTIONS

- Consider full headache differential diagnosis in all patients who present to ED with headache.
- Perform head CT and LP for patients who present with acute onset of "worst headache" to exclude subarachnoid hemorrhage.
- Administer antibiotics promptly in suspected bacterial meningitis.
- Treat pain appropriately and promptly.
- Help patients access suitable outpatient care.

Common Pitfalls

- Failure to diagnose the sentinel leak of SAH until a major bleed occurs subsequently.
- Misdiagnosis of migraine as hypertension or chronic sinusitis.

- Failure to diagnose and initiate treatment in patients with ongoing cluster headache because the acute headache has resolved prior to evaluation by the emergency clinician.
- Failure to diagnose and treat migraine appropriately either because a large tension-type component is present or because the headache is not hemicranial.
- Presuming that response to specific medications necessarily defines the etiology of a headache. The headache of brain tumors, aneurysms, and SAH may respond to a migraine regimen.

CHAPTER 154

Subarachnoid Hemorrhage

Jonathan A. Edlow

Headache is a common presenting complaint in patients presenting to the emergency department (ED). Subarachnoid hemorrhage (SAH), which comprises less than 1% of ED headaches, is a true medical emergency in that effective time-dependent treatment exists (1,2). Deciding which patients to evaluate for SAH and the components of that evaluation is therefore a critical issue for emergency physicians. The classic presentation of a thunderclap headache in a patient with a stiff neck and an abnormal mental status presents little difficulty; however approximately 40% of patients present awake, alert, and neurologically intact. Misdiagnosis in this group results in worse outcomes (1,2).

This chapter is limited to atraumatic SAH, the most common cause of which is a ruptured cerebral aneurysm or arteriovenous malformation (AVM). Approximately 2% of the general population harbors cerebral aneurysms and yet the incidence of SAH is ~8 to 10 per 100,000 (2,3). Therefore, the vast majority of aneurysms never rupture. The fact that the vast majority of aneurysms are incidental has important diagnostic implications for emergency physicians (4).

Although most unruptured aneurysms are asymptomatic, they can present with mass lesion (classically the pupil-involving third nerve palsy), headache, seizure, and cerebral ischemia. Presentation of an unruptured aneurysm as isolated thunderclap headache without SAH is rare. Aneurysmal rupture is associated with a surge in intracranial pressure (ICP) that can lead to decreased cerebral perfusion resulting in syncope, any neurologic deficit or in some cases, sudden death.

Mortality rates on the first day and first month are 12% and 40% respectively (1–3).

Blood from a ruptured aneurysm is nearly always found at the base of the brain in the basal cisterns. Emergency physicians should be aware of two other patterns (Fig. 154.1A–C). The first is a perimesencephalic SAH, in which the blood is localized to the prepontine cistern. These bleeds are nonaneurysmal and are thought to be due to venous bleeding. Angiography is negative and patient outcomes are excellent (5). The second type is the convexal SAH in which the blood is found in the subarachnoid space high up on the hemispheres. These bleeds are also nonaneurysmal and are usually due to amyloid angiopathy, reversible cerebral vasoconstriction syndrome (RCVS), or hypertension (6). The outcomes are a function of the underlying condition more than the SAH by itself (6).

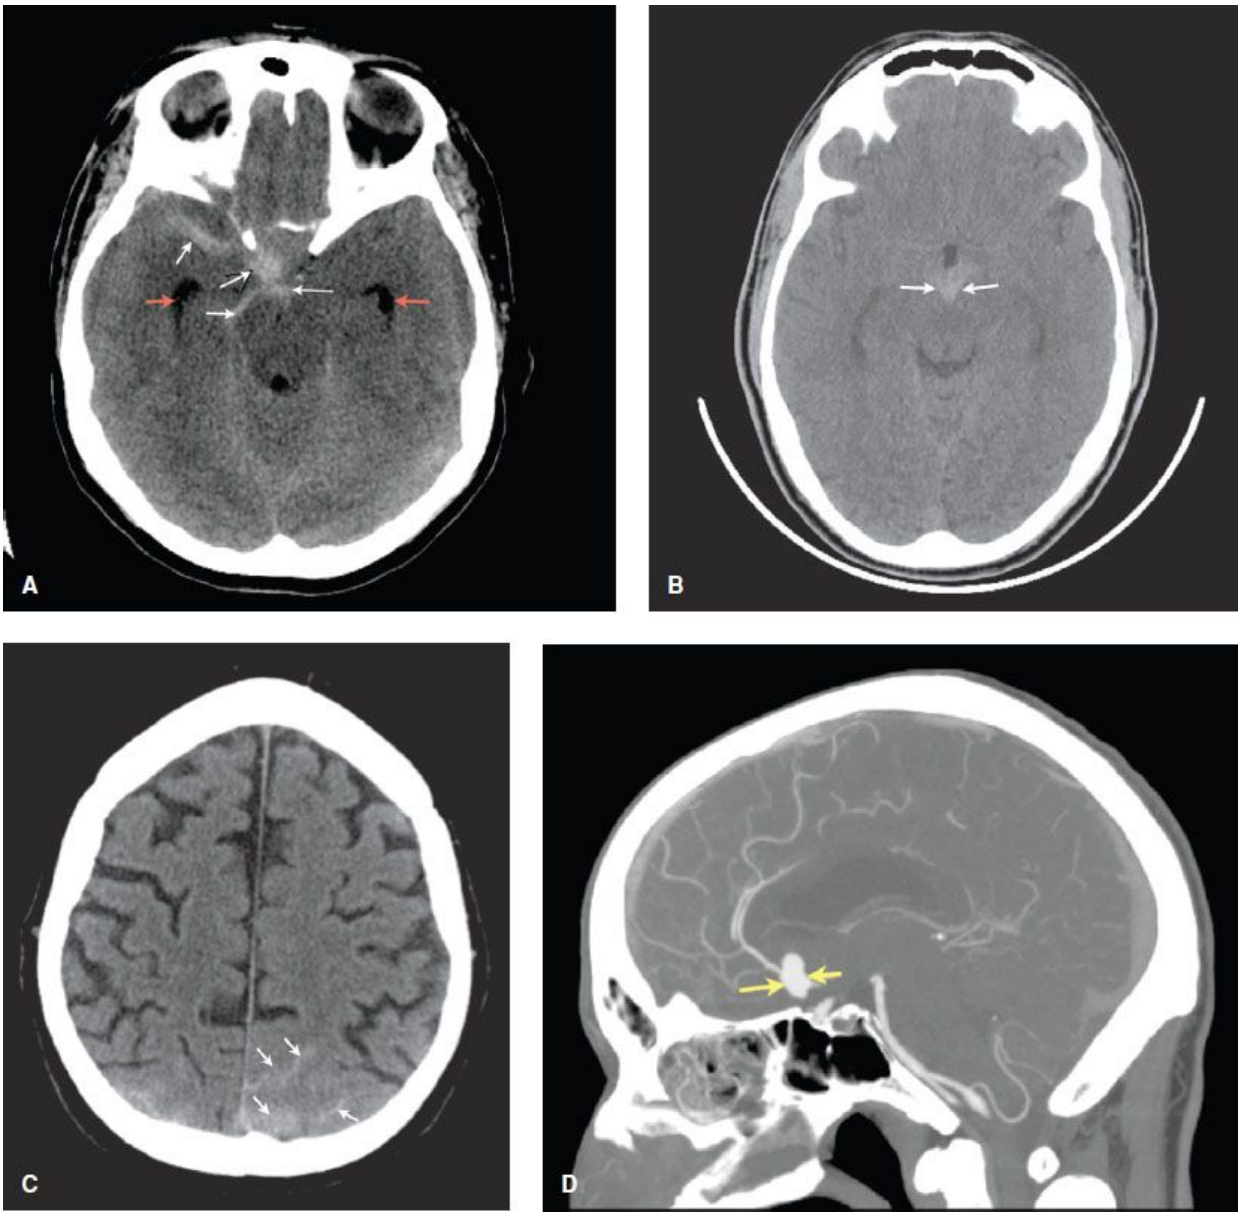

FIGURE 154.1 **A:** *White arrows* show subarachnoid blood in the basal cisterns, the typical location for a patient with an aneurysmal SAH. The *red arrows* show mild early hydrocephalus. **B:** *White arrows* show blood in the interpeduncular cistern (blood was also present in the prepontine cistern) in a patient with a perimesencephalic hemorrhage. He had a negative angiogram. **C:** *Arrows* show blood in the subarachnoid space high on the convexities in a patient with a bleed due to amyloid angiopathy. This location is also typical for reversible cerebral vasoconstriction bleeds. **D:** This is a sagittal cut of source image from a CT angiogram showing an aneurysm of the

anterior communicating artery *(yellow arrows),* a very common location for an aneurysm.

Both the American Heart Association (AHA, 2012) and the European Stroke Organization (ESO, 2013) have published recent evidence-based guidelines on SAH including detailed recommendations about the management beyond the ED phase of care (3,7).

CLINICAL PRESENTATION

There is a wide spectrum of presentations ranging from a nonacute onset headache in a neurologically intact patient to sudden death. This "bell-shaped curve" range of presentations is important for emergency physicians to know. On the right side of the curve are ill patients with an abnormal mental status and other clear-cut focal neurologic deficits. Although the specific diagnosis may not be immediately obvious, the fact that they require diagnostic testing is clear. Computed tomography (CT) of the brain is almost always an initial part of that workup and will usually reveal the problem in severely affected SAH patients. In the middle of the bell-shaped curve are patients presenting with the classic abrupt onset of a severe, unusual headache. Often, they will have had syncope at onset, be vomiting, or have prominent neck pain or stiffness. In this group too, the need for a diagnostic evaluation for SAH is clear.

Importantly however, physicians must understand the left-hand side of the curve. These patients complain of various less typical (but well described in the literature) symptoms. The headache of SAH usually is abrupt in onset, severe in intensity, and unlike other prior headaches in quality; however any of these aspects may be absent in an individual patient. Of this latter group, physicians ultimately must use their clinical judgment to decide which patients need a workup for SAH. This clinical judgment must be informed by knowledge of the range of presentations.

These presentations include abrupt onset isolated neck pain (suggesting neck strain or cervical arthritis), neck pain and low-grade fever or meningismus (viral syndrome or viral meningitis), retro-

orbital headache (sinusitis), headache with an elevated blood pressure, chest pain or an abnormal electrocardiogram (hypertensive emergency, Takosubo's cardiomyopathy, or other cardiac cause), and prominent vomiting (gastrointestinal conditions) and headache with confusion or mildly altered level of consciousness (intoxication or psychiatric diagnosis) (1,2,8–10). The severity of the SAH is often conveyed by using a clinical severity score (Table 154.1).

TABLE 154.1
Common Grading Scales Used in SAH Patients

(A) Hunt and Hess Severity Scale

Grade 1—asymptomatic, mild headache

Grade 2—moderate-to-severe headache, nuchal rigidity, no focal deficit other than cranial nerve palsy

Grade 3—mild mental status change (drowsy or confused), mild focal neurologic deficit

Grade 4—stupor or moderate-to-severe hemiparesis

Grade 5—comatose or decerebrate rigidity

(B) World Federation of Neurologic Surgeons

Grade 1—GCS 15, no motor deficit

Grade 2—GCS 13–14, no motor deficit

Grade 3—GCS 13–14, motor deficit present

Grade 4—GCS 7–12, motor deficit may be present or absent

Grade 5—GCS 3–6, motor deficit may be present or absent

(C) Fisher Scale (CT Appearance)

Group 1—no blood

Group 2—diffuse deposits of SAH blood, no clots, no layers of blood >1 mm

Group 3—local clots or vertical layers of blood ≥1 mm thickness

Group 4—diffuse or no SAH, but intracerebral or intraventricular clot

One misconception is that the onset of symptoms is always with strenuous activity. In fact, onset during sleep or quiet activity is common (1,2). The headache may not be "worst of life." As a general rule, one must consider the likelihood of other possibilities in the differential diagnosis, understanding that one cannot confidently make a diagnosis of migraine or tension-type headache after a first

ever headache. Although patients often use the term “sinusitis,” this is an unusual cause of an acute severe headache (9).

Historically, misdiagnosis of SAH is reported to occur ~20% of cases (1,2). Even in the modern era of near-universal CT access in EDs and educational focus on misdiagnosis of SAH, the rate of misdiagnosis of SAH in the ED remains 5% to 7% (2,10,11).

Based on a prospective cohort study of nearly thunderclap headache patients presenting to six Canadian EDs, a sensitive clinical decision rule has been proposed (12). Of the 2000 patients, 130 (6.5%) had SAH, making the study population representative of the spectrum seen in practice. Using recursive partitioning, they developed three clinical decision rules all of which were 100% sensitive for SAH that would have reduced the rates of investigations from 83% (baseline) to between 64% and 74% (12). The one rule that did not include the variable “arrival by ambulance” identified all SAH patients (all had at least one of the four).

- Age >40 years
- Complaint of neck pain or stiffness
- Witnessed loss of consciousness
- Onset with exertion

This clinical rule validated well in an independent population of patients although it was used somewhat differently in the second study (13).

The concept of warning bleeds is also important to consider. Some patients with SAH will have had a severe unusual headache in the days to weeks prior to being diagnosed with their SAH. These headaches have been called warning (or sentinel) bleed (or headache). Evidence suggests that these are actually small SAHs that were either not recognized by the patient or by the physician and so no evaluation (or an incomplete evaluation) was done. In a pooled analysis of 813 patients with thunderclap headache who had a negative CT and LP, none were subsequently diagnosed with SAH or died suddenly during follow-up (14). This suggests the standard workup will correctly diagnose warning bleeds.

One final point should be made regarding which patients to evaluate for SAH is the patients’ response to analgesics administered

for their headache. Because there is a final common pathway for pain sensation in the head, a patient's favorable response to any analgesic, narcotic or otherwise, including triptans, should ***not*** be used to make diagnostic inferences. The headache of patients with serious causes including SAH can improve or resolve with various analgesics including triptans.

DIFFERENTIAL DIAGNOSIS

Even among patients presenting with a thunderclap headache, only ~10% will have an SAH, most commonly from a ruptured aneurysm or AVM (2). The majority of patients with thunderclap headache have migraine and tension-type headache. A very small but important minority will have far less common but serious and treatable causes such as arterial dissection, cerebral venous sinus thrombosis (CVST), RCVS, pituitary apoplexy, and other vasculopathies.

The presence of multiple thunderclap headaches in a neurologically intact patient is nearly pathognomonic for RCVS (15). Table 154.2 shows the differential diagnosis of important treatable and serious causes of headache, of thunderclap headache, and of the vascular lesions responsible for nontraumatic SAH. Table 154.3 summarizes reasons for misdiagnosis.

TABLE 154.2
Differential Diagnoses Relevant to Patients with SAH

List of "Cannot Miss" Causes of Acute Severe Headache

- Subarachnoid hemorrhage
- Meningitis, encephalitis, and brain abscess
- Cerebral venous sinus thrombosis
- Cervical artery dissection
- Pituitary apoplexy
- Spontaneous intracranial hypotension
- Idiopathic intracranial hypertension (pseudotumor)
- Acute ischemic or hemorrhagic stroke
- Reversible cerebral vasoconstriction syndrome
- Acute narrow-angle closure glaucoma
- Temporal arteritis
- Mass lesion
  - Tumor
  - Abscess
  - Parameningeal infection
  - Intracranial hematoma
  - Colloid cyst of the third ventricle

Differential Diagnosis of Thunderclap Headache

- Subarachnoid hemorrhage
- Cerebral venous sinus thrombosis
- Cervical artery dissection
- Pituitary apoplexy
- Reversible cerebral vasoconstriction syndrome
- Hypertensive crisis
- Acute ischemic or hemorrhagic stroke
- Benign (primary) thunderclap headache (sometimes associated with orgasm, hot bath, cough, or exertion)
- Colloid cyst of the third ventricle
- Idiopathic intracranial hypotension
- Acute expansion of an unruptured aneurysm
- Intracranial infection (rarely)
- Acute sinusitis (rarely)
- Takasubo's cardiomyopathy (rarely)

Differential Diagnosis of Nontraumatic SAH

- Aneurysmal or arteriovenous malformation
- Perimesencephalic SAH
- Due to other specific vascular lesion (such as moyamoya)
- Convexal SAH
  - Amyloid angiopathy
  - Reversible cerebral vasoconstriction syndrome
  - Hypertensive crisis

TABLE 154.3
Reasons for Misdiagnosis of SAH

Failure to Know the Spectrum of Presentations of Subarachnoid Hemorrhage:

Not evaluating patients with unusual (for the patient) headaches

- Is the onset abrupt?
- Is the quality different from prior headaches?
- Is the severity greater than prior headaches?
- Are there associated symptoms that have been absent with prior headaches (such as vomiting, diplopia, syncope, or seizure)?

Failure to Appreciate that the Headache Can Improve Spontaneously or with Nonnarcotic Analgesics

Overreliance on the classic presentation with misdiagnosis of:

- Viral syndrome, viral meningitis and gastroenteritis
- Migraine and tension-type headache
- Sinus-related headache
- Neck pain (rarely, back pain)
- Psychiatric diagnoses

Focus on the secondary head injury (resulting from syncope and fall or car crash)

Focus on the electrocardiographic abnormalities

Focus on the elevated blood pressure

Lack of knowledge of presentations of the unruptured aneurysm

Failure to Understand the Limitations of Computerized Tomographic (CT) Scans:

CT scans are less sensitive with increasing time from onset of headache

CT scan can be falsely negative with small volume bleeds (spectrum bias)

Interpretation factors (expertise of physician reading the scan)

Technical factors (Have thin cuts been taken at the base of the brain? Is there motion artifact?)

CT can be falsely negative for blood at hematocrit level of less than 30%

Failure to Perform Lumbar Puncture and Correctly Interpret Cerebrospinal Fluid Findings:

Failure to do lumbar puncture in patients with negative, equivocal, or suboptimal CT scans

Failure to recognize that xanthochromia may be absent very early (<12 h) and very late (>2 wks)

Failure to understand the performance characteristics of xanthochromia measurement

Failure to properly distinguish traumatic tap from true subarachnoid hemorrhage

ED EVALUATION

For decades, the standard ED evaluation has been CT followed by lumbar puncture (LP) if the CT is nondiagnostic. As of mid-2013, in guidelines published by ACEP, the AHA and the ESO, this recommendation stands (3,7,16). Large studies confirm the safety and the sensitivity of this protocol (14,17).

A key point is to realize that the sensitivity of CT and LP changes with the time elapsed from the onset of the bleed and the performance of the test (1,2,8). CT is an excellent test early but the sensitivity degrades rapidly with time. LP and cerebrospinal fluid (CSF) analysis shows blood early in the course of a SAH. Increasing numbers of RBCs in the fourth tube and low percent change in RBCs from tube 1 to tube 4 are the most useful to predict SAH (18,19). Xanthochromia (the yellow color of CSF due to hemoglobin breakdown) takes time to develop but is usually present for up to 2 weeks after the bleed. Nearly all North American hospital laboratories use visual inspection for xanthochromia (20). Studies support the notion that measuring xanthochromia by visual inspection is a valuable method and that spectrophotometry, while more sensitive, lacks specificity (21,22).

Newer data about older techniques (early CT) and greater availability and data about newer techniques—CT angiography (CTA), magnetic resonance imaging (MRI), and MR angiography (MRA)—are beginning to impact the diagnostic paradigm for SAH (Fig. 154.1D). Each of these testing strategies has both advantages and limitations compared to the time-honored CT followed by LP (Table 154.4). Although official guidelines do not reflect it, the preponderance of data suggest that a normal CT performed within 6 hours of headache onset and interpreted by an experienced attending level radiologist excludes SAH with close to 100% sensitivity and that LP is no longer required in this setting (23–25).

TABLE 154.4
Diagnostic Strategies

Diagnostic Strategy	Advantages	Disadvantages
CT + LP	Time-honored method Very sensitive to SAH (CT has excellent sensitivity early; LP has excellent sensitivity later) Recommended by all current guidelines	Traumatic tap occurs in ~20% of LPs and can confuse the diagnosis No standard number of RBCs Different methods to detect xanthochromia
LP first	Forces the LP, which is otherwise not done in many cases in routine practice Will diagnose other causes that cause abnormal CSF	May miss pathology only visible on CT and which is associated with normal CSF Risk of herniation if patients are not carefully examined and selected
CT only (no LP if <6 h)	Avoids a painful, invasive procedure Saves time	Will miss some diagnoses that are only diagnosable by CSF examination May miss as much as 4/1,000 true SAHs
CT + CTA	Rapid Accurately diagnoses aneurysms	Additional radiation exposure Adverse reactions to contrast media Will diagnose incidental aneurysms
MRI	MRI is sensitive for acute blood MRI is also very sensitive for chronic blood, helping to diagnose older bleeds	Expense and availability If not followed by LP, the issue of spectrum bias still occurs (in which a bleed is too small to be positive, same as with CT) Radiologists are less familiar with technique and correct sequences must be obtained
MRI + MRA	Same as above Accurately diagnoses aneurysms	Same as above Will diagnose incidental aneurysms

CT, computed tomography (noncontrast); LP, lumbar puncture; SAH, subarachnoid hemorrhage; RBCs, red blood cells; CSF, cerebrospinal fluid; CTA, CT angiography; MRI, magnetic resonance imaging; MRA, magnetic resonance angiography.

A recent study reported instances of CT-negative LP-positive patients (CT done within 6 hours) but the data as reported make it unclear how many of their "SAH" patients truly had SAH nor how many patients in the early presenting group had positive CT scans. Another study of early CT-negative patients found no patients with aneurysmal SAH among those presenting early (26).

For the strategies that include an angiogram, it is important to recognize that many of these aneurysms will be incidental. Approximately 2% of the general population has cerebral aneurysms. Since most patients with SAH have a positive CT, a "positive" CTA in a CT-negative patient makes it even more likely that the aneurysm is incidental. A CTA or MRA that diagnoses (what is actually) an incidental lesion can lead to an unnecessary procedure on the one hand, or a lot of anxiety and subsequent imaging on the other (4). For CTA, there are also considerations of radiation and dye complications (4).

Whatever diagnostic algorithm is used, one must factor in time from headache onset and understand the limitations of the tests.

KEY TESTING

- Noncontrast brain CT
- LP if CT is nondiagnostic
- Consider other testing algorithms; however each has limitations that must be explicitly addressed (Table 154.4)

ED MANAGEMENT

As always, initial attention to airway, breathing and circulation takes priority. Most patients with SAH do not require intubation. If an SAH patient needs airway control, standard rapid sequence intubation is used. For patients being transferred to another facility, one must consider the possible need for airway control over the duration of time of the transfer.

With regard to blood pressure control, the data are poor quality in terms of a specific target blood pressure. The 2012 AHA recommends that the systolic blood pressure be kept at less than 160 mm Hg and

the 2013 European ESO recommends that the systolic pressure be kept below 180 mm Hg. However many practitioners aim for a lower number. Both the AHA and ESO caution that the data are poor and that more important than a specific one-size-fits-all pressure, the clinicians must balance issues such as cerebral perfusion, risk of rebleeding, premorbid blood pressure, and other factors. Whatever target is used, use an antihypertensive intravenous easy-to-titrate drug such as nicardipine, esmolol, or labetalol.

With the ABCs covered, and the causative vascular lesion defined as above, there are a number of other issues that the emergency physician must consider. Pain and anxiety should be treated. Patients should be placed on telemetry and have a 12-lead electrocardiogram. Intravenous access should be established and blood should be sent for testing to the laboratory for routine hematologic and chemistry tests as well as tests of clotting and troponins. Other management issues should all be discussed and resolved with the accepting neurovascular specialist. These include treatment of seizures and hydrocephalus, vasospasm prophylaxis, the timing and choice of cerebrovascular imaging, and administration of short-term antifibrinolytics (Table 154.5).

TABLE 154.5
Treatment Approach

1. Airway management if indicated
2. Specialist consultation and arranging an angiogram
3. Arrangement for transfer to a neurovascular center
4. Management of hypertension
5. Volume status and intravenous fluids
6. Seizure treatment
7. Acute treatment of hydrocephalus, extra-axial or intracerebral hematomas
8. Nimodipine administration for vasospasm prophylaxis
9. Discuss short-term antifibrinolytics to prevent rebleeding
10. Cardiac telemetry
11. Analgesia
12. Treatment of elevated ICP

When SAH is diagnosed, rapidly consult with a cerebrovascular expert. This discussion should consider the points above on a case-by-case basis.

If a patient with SAH deteriorates while still in the ED, repeat the CT. There may be little to do for a massive rebleed or large territorial cerebral infarction from vasospasm; however, in some cases, acute hydrocephalus or a space-occupying bleed may be amenable to surgical intervention. In cases in which the CT is unchanged, consider nonconvulsive status epilepticus, cerebral hypoperfusion from overly aggressive lowering of the blood pressure or side effects of analgesics or anxiolytics.

Controversies

- Avoiding LP in the evaluation of SAH in patients who present typically with thunderclap headache and have a noncontrast CT scan performed within 6 hours of headache onset that is read as negative by an attending radiologist
- Ideal level of blood pressure control is unclear
- Seizures should be treated; however, prophylactic anticonvulsants are not indicated
- Administration of short-term antifibrinolytics (after diagnosis but before definitive treatment) to prevent early rebleeding may be considered

CRITICAL INTERVENTIONS

- Control airway using standard rapid sequence technique if clinically indicated
- Whatever diagnostic algorithm is used, follow it to its completion
- When controlling blood pressure, factor in premorbid blood pressure and current cerebral perfusion pressure
- Repeat CT scan for SAH patients who deteriorate while in the ED to identify a reversible cause
- Patients with SAH should be admitted to a facility with experience in SAH

DISPOSITION

Patients with SAH should be admitted to an ICU. Based on data over the past decade, the AHA recommends that patients with aneurysmal

SAH be treated in a high-volume center (defined as one that manages >35 cases per year) (3). The improved outcomes likely result not only from the technical expertise of the interventionalist and/or surgeon, but also the multidisciplinary neurointensive care that is available. Increasing numbers of SAH patients are being treated by endovascular coiling.

Common Pitfalls

- Failure to consider SAH in a patient with headache because they "do not appear ill" or "have a normal level of consciousness and neurologic examination," that is, failure to understand the spectrum of presentations
- Failure to fully workup patients with thunderclap headache for SAH
- Assuming that a patient with a severe headache whose pain has improved with analgesics does not have a serious cause of headache
- Failure to understand the limitations of CT, LP, and MRI, especially with regard to "timing" of the test compared to the onset of symptoms
- Failure to refer a patient with an SAH to a high-volume neurovascular center where patient outcomes are demonstrably better

CHAPTER 155 Cerebrovascular Disease

Phillip A. Scott

The term *stroke* refers to the sudden onset of a neurologic deficit caused by an acute vascular lesion of the brain that is hemorrhagic, embolic, thrombotic, or aneurysmal in nature. *Cerebrovascular disease* is a broader term, encompassing stroke and other vascular causes of central nervous system dysfunction.

ISCHEMIC CEREBROVASCULAR DISEASE

Ischemic neurologic deficits are commonly categorized by their time course. A transient deficit, not accompanied by tissue infarction, is considered a *transient ischemic attack* (TIA), with the majority resolving within 60 minutes of onset (1). By extension, the presence of cellular loss on advanced imaging, typically accompanied by persistent clinical signs, defines infarction—that is, *stroke.* Other classification systems define stroke syndromes by probable cause or anatomic location.

Risk Factors

Not surprisingly, risk factors for ischemic cerebrovascular disease parallel those for atherosclerotic heart disease. Hypertension, diabetes, and coronary artery disease substantially increase the risk of stroke. Left ventricular hypertrophy, atrial fibrillation, and acute myocardial infarction (AMI) are also independent risk factors for ischemic stroke.

There are significant associations of ischemic cerebrovascular disease with age, gender, and race. The incidence of all strokes

increases with age, doubling with each decade of life. There is a slightly higher risk in men as compared with women, and black men and women have an overall age- and sex-adjusted stroke incidence rate 1.5 times higher than whites.

Medical conditions predisposing to stroke include a history of migraine headaches, elevated fibrinogen levels or hematocrit (causing increased blood viscosity), and advanced age with elevated total serum cholesterol levels.

Environmental risk factors for ischemic cerebrovascular disease include smoking and heavy alcohol consumption. Women taking oral contraceptives, particularly high-estrogen formulations, are also at increased risk for stroke. This risk is more pronounced in female smokers older than 35 years of age and in those with other cardiovascular risk factors.

Finally, patients with a history of ischemic stroke represent a high-risk population, with 1- and 5-year recurrence rates among survivors of 10% and 20%, respectively.

TRANSIENT ISCHEMIC ATTACK

There is a higher risk of early stroke following TIA than previously thought. Ten percent to 15% of patients with TIA have a stroke within 3 months, with half experiencing a stroke within 48 hours of the initial TIA (1).

TIAs may result from plaque ulceration or embolism of platelet aggregates from extracranial or intracranial atherosclerosis. After impeding local blood flow, these emboli break up, accounting for the transient nature of the episode. Other sources of emboli include prosthetic heart valves and infective or marantic vegetations on valve leaflets. Small vessel disease in penetrating cerebral arteries may actually be the most common cause of TIAs and that these “lacunar” TIAs may represent a subgroup with a better prognosis than TIAs with cortical symptoms. Hypotension and mechanical kinking of the extracranial vessels are less common causes of TIAs. Cardiac dysrhythmias are an important potential etiology for the emergency physician to consider.

CLINICAL PRESENTATION

Carotid artery syndrome results from transient disruption of the anterior circulation of one cerebral hemisphere or of the retina. Hemispheric ischemia results in an abrupt onset of contralateral monoparesis or hemiparesis, numbness, tingling, aphasia, or hemianopia. Occlusion of the ophthalmic branch of the internal carotid artery results in retinal ischemia, causing temporary monocular blindness (amaurosis fugax). The patient complains of a "fog," "mist," "cloud," or "shade being drawn" over the visual field of one eye. Funduscopic examination of the involved eye may reveal cholesterol crystals (Hollenhorst plaques) in the retinal vessels.

Transient ischemia involving the posterior circulation (the brainstem or occipital lobes) is termed *vertebrobasilar artery syndrome.* Interruption of brainstem circulation may result in symptoms of vertigo, dizziness, ataxia, nausea, or vomiting secondary to involvement of the vestibular nuclei. Dysarthria, dysphagia, and perioral numbness may also occur. Occipital lobe ischemia results in blurred or dim vision or total cortical blindness. Diplopia may result from loss of conjugate gaze.

Basilar artery TIAs may cause *drop attacks*—brief paretic spells resulting in the patient's dropping to his or her knees. There is no loss of consciousness, distinguishing it from true syncope, and the patient attempts to rise immediately after falling.

Transient global amnesia (see Chapter 157, "Transient Global Amnesia") is thought to be caused by ischemia of the temporal lobes or thalamic area supplied by the posterior cerebral arteries. These episodes affect men more frequently than women and are characterized by a rapid development of retrograde memory loss and confusion, with preservation of self-identity. The length of retrograde amnesia gradually shortens until only the period during the attack remains lost.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TIAs includes transient deficits secondary to mass lesions from either tumor or hemorrhage (these patients often have a residual neurologic deficit detectable on

examination); infection (as with focal abscess, septic emboli, meningitis, or encephalitis); seizure with a subsequent Todd paralysis; complicated migraine; exacerbation of multiple sclerosis; hypoglycemia; and syncope from any cause, particularly cardiac dysrhythmias.

ED EVALUATION

Clinical investigation of a TIA is directed toward identifying whether the deficit involves the anterior or posterior circulation, establishing the source of the TIA, and ruling out other causes of focal deficits. A detailed history often provides the most significant information. The patient may not be aware of any deficits, and the family should be questioned, if possible, along with the patient. The onset and course of symptoms should be carefully elicited. Were there any prior episodes? If so, how many? Were the events in the same or differing vascular distributions?

The neurologic examination in patients with TIAs is often unremarkable, but a thorough assessment is essential. Orthostatic blood pressures should be measured in patients with vertebrobasilar TIAs, because symptoms are often related to postural changes. Auscultation for cervical and subclavian bruits should be performed, as should evaluation for cardiac dysrhythmias, murmurs, and left ventricular dysfunction.

Determination of the $ABCD^2$ score may assist in predicting short-term risk of stroke in patients presenting with TIA. Patients are assessed on points based on age $\leq$60 years (1 point); blood pressure $\leq$140/90 mm Hg on initial evaluation (1 point); clinical symptoms of weakness (2 points) or speech impairment without weakness (1 point); duration 10 to 59 minutes (1 point) or $\leq$60 minutes (2 points); and diabetes (1 point). The 48-hour risk of stroke was 0% for scores of 0–1, 1.3% for 2–3, 4.1% for 4–5, and 8.1% for 6–7 (2).

KEY TESTING

Laboratory Testing	• CBC with platelets • Chemistry panel with glucose • Prothrombin time and partial thromboplastin time • Consider erythrocyte sedimentation rate and C-reactive protein if vasculitis suspected • Consider specialized coagulation testing in younger patients with TIAs
Cardiac Evaluation	• EKG • Consider prolonged cardiac monitoring in patients with unclear TIA origin • Consider echocardiography in patients where no other cause has been identified
Neuroimaging Options	• CT • MRI with diffusion-weighted imaging (DWI)
Vascular Imaging Options	• Carotid ultrasound • CT angiography • MR angiography

ED MANAGEMENT

Medical therapy is indicated for patients with posterior circulation TIAs, patients with anterior circulation TIAs who have <50% stenosis on carotid duplex scanning, and patients who are not candidates for carotid endarterectomy. Medical treatment options are limited to antiplatelet therapy and anticoagulation.

Acceptable options for initial antiplatelet therapy in patients with TIA include the following:

- Aspirin (50 to 325 mg/d) monotherapy
- Extended-release dipyridamole combined with aspirin (Aggrenox)
- Clopidogrel (Plavix) monotherapy (75 mg/d)
- Clopidogrel (300-mg loading dose) combined with aspirin (75 mg)

Antiplatelet therapy with aspirin (50 to 325 mg/d) reduces the incidence of nonfatal stroke, nonfatal myocardial infarction, and death from all vascular causes in patients with TIAs. Because the lower dosages require several days to achieve maximal platelet inhibition, therapy in the early setting should be initiated with 300

to 325 mg/d. The combination of dipyridamole plus aspirin (Aggrenox) was modestly better than aspirin alone; however, a number of patients discontinue combination therapy owing to medication intolerance (3,4).

Clopidogrel is an ADP-inhibitor and also acceptable as monotherapy for patients with TIA. Its role as a primary or secondary agent in the treatment of TIA is debated, given its cost and the small (0.5%) absolute improvement in reducing risk for the combined end point of stroke, AMI, and vascular death in patients with atherosclerotic vascular disease compared to aspirin alone (5). The combination of clopidogrel with aspirin was superior to aspirin alone in preventing recurrent stroke in patients with TIA or minor stroke (8.2% vs. 11.7%) in a large Chinese study (6). A companion trial is currently underway in the United States (7).

The use of anticoagulation in patients experiencing noncardioembolic TIA lacks a rigorous scientific basis. Though heparin has traditionally been used in select patients with TIA, no prospective randomized study of significant size has demonstrated a clear benefit and its use cannot be recommended on the basis of existing data. If used at all, it should be reserved for “high-risk” patients such as those with crescendo TIAs, vertebrobasilar TIA, recurrent TIA while receiving maximum antiplatelet therapy, high-grade carotid stenosis, or a suspected cardiac source for emboli. Neurologic consultation is recommended prior to initiation.

Adjusted-dose oral anticoagulation with warfarin has been the predominant treatment for stroke prevention in patients with a cardioembolic TIA due to atrial fibrillation. A target international normalized ratio (INR) of 2 to 3 is recommended. The efficacy of aspirin is considerably less than warfarin in this population and is recommended as an alternative for those with contraindications to oral anticoagulation. Newer oral anticoagulants inhibiting thrombin or factor Xa have demonstrated improved stroke prevention with comparable safety to warfarin. The lack of an available antidote has raised concern over their use. Anticoagulant therapy may be appropriate for patients with other sources of cardiogenic emboli

who have a TIA; however, randomized clinical trials have not been performed in these specific patient populations.

A subset of patients with TIA has surgically correctable carotid stenosis and represent an important group for the emergency physician to identify. Those with ≥50% carotid stenosis are potential candidates for endarterectomy and should receive medical therapy in the ED pending a decision on vascular intervention.

CRITICAL INTERVENTIONS

- Initiate antiplatelet therapy for patients with TIA.
- Identify and refer patients with surgical or endovascular correctable carotid stenosis.

DISPOSITION

Patients who have a new anterior circulation TIA and are potential surgical candidates should not be discharged without arranging expeditious evaluation of the carotid arteries. If duplex scanning is not immediately available, the patient should be started on antiplatelet therapy and carotid duplex scanning performed as soon as possible, with subsequent vascular consultation for patients determined to have stenosis of 50% or more.

Because of the increased short-term risk of stroke, it may be optimal to admit patients with TIA to an inpatient or observation bed. Current guidelines state it is reasonable to hospitalize patients with TIA if they present within 72 hours of the event and have either an $ABCD^2$ score ≤3; $ABCD^2$ score of 0–2 and inability to complete diagnostic workup as outpatient within 2 days; or an $ABCD^2$ score of 0–2 and other evidence indicating the event was caused by focal ischemia (2). The clinical utility of the $ABCD^2$ score in the emergency department setting, however, has been questioned owing to its low sensitivity and specificity (8). Admission and neurologic consultation should be considered for high-risk patients. Standard protocols for patients with TIAs should be jointly developed with neurologic specialists in each institution. Active collaboration can

ensure the provision of efficient and consistent patient care and facilitate future modifications as new data become available.

Common Pitfalls

- Discharging patients with anterior circulation TIAs before determining whether there is a potentially surgically correctable carotid lesion. This carries a high medicolegal risk.
- Failure to obtain consultation in high-risk patients: Those with crescendo TIAs, vertebrobasilar TIA, recurrent TIA on maximal antiplatelet therapy, high-grade carotid artery stenosis, or presumed cardioembolic source.
- Failing to discuss signs and symptoms of stroke with the patient and emphasizing the need to immediately return for recurrent symptoms.

ISCHEMIC STROKE

Ischemic strokes have traditionally been classified by clinical presentation, time course of onset, progression of deficits, accompanying symptoms, and risk factor profiles. The clinical description of the deficit identifies the extent and location of the stroke and allows accurate communication regarding patient status. The time course and progression of symptoms suggest certain etiologies; for example, prolonged, "stuttering" deficits indicate a thrombotic phenomenon, whereas an abrupt onset of the maximal deficit suggests an embolic event. Associated symptoms may suggest other causes for neurologic deficits (e.g., a seizure preceding a Todd paralysis or chest pain preceding an ischemic stroke of cardioembolic origin). Consideration of cerebrovascular risk factors helps to classify the stroke as lacunar, embolic, thrombotic, extracranial, or intracranial.

CLINICAL PRESENTATION

Anterior Cerebral Artery Syndrome

Patients with infarction in the territory of the anterior cerebral artery present with hemiparesis involving the leg more than the face or

arm. Urinary incontinence and primitive reflexes (grasp and suck) are often present. The patient may perseverate with speech or motor movements and respond slowly to questions. If both anterior cerebral arteries originate from a common trunk, a bilateral parasagittal infarct may occur, with paraplegia and speechlessness (anarthria).

Middle Cerebral Artery Syndrome

Infarction in the distribution of the middle cerebral artery is the most common of the stroke syndromes. Patients with infarcts of the middle cerebral artery present with weakness of the face and arm greater than that of the leg, often with corresponding cortical sensory loss. The presence of aphasia localizes the lesion to the dominant hemisphere. Inattention, extinction on double simultaneous sensory or visual testing, neglect, or constructional or dressing apraxia indicates nondominant hemisphere involvement. Homonymous hemianopia and conjugate eye deviation toward the side of the infarct may also be found. All of these findings are present in the patient with a proximal trunk occlusion and variably present when branches of the middle cerebral artery are involved.

Posterior Cerebral Artery Syndrome

Infarcts in the posterior cerebral artery territory present with homonymous hemianopia secondary to visual cortex involvement. The patient is often unaware of the deficit until formally tested. Motor involvement is minimal, but sensory loss, including both light touch and pinprick, may be severe. There is no aphasia or disruption of nondominant hemisphere functions. Small branches of the posterior cerebral artery anastomose with branches of the anterior and middle cerebral arteries in border zones between the arterial distributions. These areas are at risk for *watershed infarcts* during periods of decreased blood flow.

Vertebrobasilar Artery Syndrome

The classic sign of brainstem stroke is the presence of crossed symptoms: Ipsilateral cranial nerve palsy and contralateral

hemiplegia. One of the most common strokes in this region is due to occlusion of the vertebral or posterior-inferior cerebellar artery, resulting in the *lateral medullary (Wallenberg) syndrome.* Patients may present with ipsilateral facial pain (described as a sharp or stabbing sensation to the face or eye), vertigo, headache, limb ataxia, Horner syndrome, and weakness of the soft palate, with dysphagia and dysphonia. Contralateral symptoms include loss of pinprick and temperature sensation in the arm and leg. Other brainstem syndromes may result in deafness, nausea, vomiting, vertigo, and diplopia.

Cerebellar Infarction

A subset of posterior circulation strokes involves the cerebellum. The most common initial symptom is the sudden inability to walk or stand. This may be followed by complaints of headache, nausea, vomiting, central vertigo, and, possibly, a stiff neck. Cranial nerve findings may also be present. Although the initial CT scan is often unremarkable, one-third of patients develop significant posterior fossa edema. In this confined space, edema produces pressure on the brainstem, causing a decrease in the level of consciousness, typically after a stable period of 6 to 12 hours. Pathologic respiratory patterns and pupillary dilation are late findings, indicating impending herniation. Recognition of cerebellar infarction is critical, and frequent neurologic assessment is imperative. Repeat CT scanning or magnetic resonance imaging (MRI) is indicated for patients with a declining level of consciousness. Surgical decompression and/or medical treatment of elevated intracranial pressure (ICP) may be lifesaving.

Lacunar Syndromes

Lacunar infarcts cause several distinct stroke syndromes. Lacunes are found almost exclusively in the basal ganglia, internal capsule, thalamus, and brainstem and are associated with hypertensive arteriopathy. Approximately 20% of patients with lacunar infarctions have had a prior TIA, and the onset of symptoms is often surprisingly

gradual (>36 hours in up to 30% of patients). Deficits often improve with time, and treatment is aimed at control of hypertension after the acute episode resolves. An evaluation for embolic sources should also be undertaken. Lacunar strokes are classified by clinical presentation.

The most frequent lacunar syndrome, *pure motor stroke,* causes paresis/paralysis of the face, arm, and leg. It is easily diagnosed when the deficit involves all three areas equally but may also present as a partial deficit. The location of the lacune may be in the internal capsule or pons. Cortical sensory deficits are notably absent.

Pure sensory stroke is the result of infarction of the ventral posterior nuclei of the thalamus and results in sensory loss in the face, arm, and leg. The patient may also complain of paresthesias involving the affected side. There is no hemiplegia or other cortical sign.

Patients with *clumsy hand–dysarthria syndrome* present with slurred speech and weakness and ataxia of the upper limb. Facial weakness may also be present. The syndrome is most commonly associated with lesions of the anterior limb and genu of the internal capsule and typically has a good functional outcome.

DIFFERENTIAL DIAGNOSIS

Table 155.1 lists conditions that may mimic ischemic stroke and is divided into structural and nonstructural diseases. Neuroimaging is used initially to evaluate these possibilities and to rule out structural causes of neurologic deficits.

TABLE 155.1
Differential Diagnosis of Ischemic Stroke

Structural Causes	Nonstructural Causes
Intracerebral hemorrhage	Meningitis
Epidural hematoma	Encephalitis
Subdural hematoma	Hypertensive encephalopathy
Intracranial tumor	Wernicke encephalopathy
Intracranial abscess	Hypoglycemia
	Complicated (hemiplegic) migraine
	Todd postictal paralysis
	Peripheral nerve palsy (Bell palsy)
	Labyrinthitis
	Ménière's disease
	Demyelinating disease (multiple sclerosis)
	Drug toxicity (phenytoin, lithium)

Diseases presenting with features similar to posterior circulation strokes can be difficult to distinguish from stroke. Wernicke encephalopathy presents as the triad of ophthalmoplegia, ataxia, and confusion and is found typically in chronic alcoholics. Ménière's disease, with its characteristic triad of vertigo, tinnitus, and deafness, occurs in patients between the ages of 30 and 60 and is paroxysmal in nature. Gross ataxia and other cranial nerve deficits should be absent. Multiple sclerosis typically presents in the third to fourth decades of life and has variable symptoms, depending on the location of demyelination. Symptoms of phenytoin and carbamazepine toxicity include sedation, nystagmus, vertigo, ataxia, and nausea. Central nervous system symptoms of acute lithium toxicity include confusion, hyperreflexia, tremors, and cranial nerve deficits; dysarthria also may be a prominent feature.

Special consideration should be given to stroke patients younger than 50 years of age or those who have pre-existing heart disease, hematologic disorders, or vasculitis. These patients typically fall into the cardioembolic, other, or unknown subtype classifications and may have reversible etiologies or other contributing disease states that should be identified as rapidly as possible. Conditions associated with each of these groups are listed in Table 155.2.

TABLE 155.2
Differential Diagnosis of Special Patient Groups with Ischemic Stroke

Condition	Comments
Young Adults with Stroke	
Arterial dissection	Age between 15 and 50 Accounts for 20% of strokes in the young, often preceded by minor trauma
Cardioembolism	Mitral valve prolapse, patent foramen ovale with paradoxical emboli, rheumatic heart disease
Premature atherosclerosis	Hyperlipidemia
Migrainous stroke	Female predominance
Air embolism	Scuba diving, medical procedures
Substance abuse	Heroin, cocaine, amphetamines, LSD
Pre-Existing Cardiac Disease	
Ischemic heart disease	Peripheral emboli from mural thrombus
Dysrhythmias	Atrial fibrillation, ventricular tachycardia, sick sinus syndrome, etc.
Valvular heart disease	Rheumatic heart disease, prosthetic valves
Dilated cardiomyopathies	Peripheral emboli from mural thrombus
Endocarditis	Associated fever and murmur
Hematologic Disorders	
Hyperviscosity syndromes	Cancer, myeloproliferative diseases, dysproteinemia, thalassemia, sickle cell disease, polycythemia
Coagulopathies	Disseminated intravascular coagulation, protein C or S deficiencies, antithrombin III deficiency, antiphospholipid antibody syndrome
Thrombotic thrombocytopenic purpura	Rare disorder with fever, microangiopathic hemolytic anemia, thrombocytopenia, neurologic and renal impairment
Vascular Disorders	
Infectious vasculitis	Herpes zoster, human immunodeficiency virus infection, syphilis, tuberculosis, aspergillosis
Noninfectious vasculitis	
Necrotizing	Polyarteritis nodosa
Nonnecrotizing	Giant cell arteritis (patients >age 50; females > males), Takayasu arteritis
Cerebral venous thrombosis	Presents with headache and papilledema; magnetic resonance imaging is diagnostic

ED EVALUATION

Like myocardial infarction, stroke is an acute disease necessitating early identification and treatment. Prehospital personnel should obtain information surrounding the onset of symptoms, and particularly noting the time deficits started ("last seen normal" time). Patients found lying immobile for prolonged periods are at risk for decubitus ulcers, dehydration, hypothermia or hyperthermia, and rhabdomyolysis. Intravenous access should be obtained and a fingerstick glucose level determined. In the prehospital phase, it is unusual for patients with ischemic stroke to have an altered level of consciousness; an altered sensorium suggests other etiologies. Glucose-containing solutions and routine administration of dextrose (D_{50}) should be avoided unless hypoglycemia is documented or strongly suspected. Narcan is generally not required unless there are historic features or pinpoint pupils, suggesting opiate ingestion.

On arrival in the ED, stroke patients require a monitored bed and rapid assessment of airway, breathing, and circulatory status. Complete vital signs should be obtained, including a core temperature. A focused physical examination should be performed, including a search for evidence of head trauma. The neck should be examined for meningeal signs present with either infection or subarachnoid hemorrhage (SAH). Auscultation for carotid bruits, particularly on the side opposite a clinical deficit, should be performed. The heart is examined for rate, regularity, and murmurs, searching for conditions predisposing to stroke, such as atrial fibrillation and mitral valvular disease. The extremities should be assessed for evidence of peripheral vascular disease or emboli and the skin examined for needle tracks or evidence of petechiae or ecchymosis, suggesting endocarditis, sepsis, or coagulopathy.

The neurologic examination should include a brief assessment of mental status, including level of consciousness, language, memory, and interpretation. A careful eye examination should follow, with testing of both visual acuity and visual fields. Pupillary size, reactivity, and extraocular movements provide information on brainstem function and cranial nerves III, IV, and VI. Anisocoria suggests a third nerve palsy, potentially from elevated ICP, and

should be investigated with a “swinging flashlight” test. Conjugate eye deviation toward the normal arm and leg suggests a hemispheric lesion, whereas deviation toward the paretic arm or leg suggests a brainstem lesion. Funduscopic examination of the retina may reveal papilledema, hypertensive changes, Hollenhorst plaques, diabetic changes, or Roth spots suggestive of specific stroke etiologies. Cranial nerves V and VII through XII may quickly be assessed by examining facial and corneal sensation; smiling symmetry, eyebrow raising, and forehead wrinkling; gross auditory acuity; gag reflex; shoulder shrug (trapezius strength); head rotation against resistance (sternocleidomastoid strength); and tongue protrusion, respectively.

Motor strength and tone should be assessed in both proximal and distal muscle groups. Pronator drift is a sensitive indicator of upper extremity weakness.

The sensory examination is the most subjective part of the neurologic examination and should be interpreted in view of the patient’s ability to cooperate and the overall examination. Double simultaneous extinction is tested at this time, particularly if visual field deficits were identified. The ability of a patient to identify, by touch, common objects such as keys or pens (stereognosis) and to identify a number drawn on the skin surface (graphesthesia) is an easy test of sensory function done in the ED.

Cerebellar function can be assessed by finger-to-nose and heel-to-shin tests; these are particularly useful with the bedridden patient. Important reflex arcs to test include the biceps (C5, C6), triceps (C6, C7, C8), patellar (L2, L3, L4), and Achilles (L5, S1), and pathologic reflexes. Asymmetry of deep tendon reflexes or a unilateral Babinski sign may indicate corticospinal tract lesions.

Assessment of station and gait is one of the most revealing parts of the neurologic examination. Subtle weakness, ataxia, rigidity, and sensory defects can be identified by observation of the gait, toe walking, heel walking, tandem walking, and Romberg tests.

KEY TESTING

All patients:

- Noncontrast brain CT or brain MRI

- Blood glucose
- Oxygen saturation
- Serum electrolytes/renal function tests
- Complete blood count, including platelet count
- Cardiac enzymes
- Coagulation studies (prothrombin time/INR/activated partial thromboplastin time)
- EKG

Selected patients:

- Thrombin time and/or ecarin clotting time if patient suspected of taking direct thrombin inhibitors or factor Xa inhibitors
- Liver function tests
- Toxicology screens
- Blood–alcohol level
- Blood cultures (if febrile, or infectious etiology suspected)
- Serum creatine phosphokinase and/or urine myoglobin (if rhabdomyolysis suspected)
- Pregnancy test
- Arterial blood gas
- Chest x-ray (if pulmonary disease suspected)
- Lumbar puncture (if SAH is suspected and CT scan is negative)
- Electroencephalogram (if seizures suspected)

Noncontrast CT imaging will provide the information necessary for most emergent treatment decisions. An ischemic stroke does not become hypodense for 6 to 72 hours after vessel occlusion and is often not visible on initial CT evaluation. If CT scanning is unavailable, the patient should be stabilized and transferred as rapidly as possible to a facility with CT capability.

Multimodal CT (combining noncontrast brain CT with CT angiography and/or CT perfusion mapping) provides further vascular and tissue information and can enhance both diagnostic and management decisions. Disadvantages include an increased time to image acquisition and interpretation, the use of iodinated contrast, and additional radiation exposure. Multimodal MRI also provides enhanced information but typically plays a more limited role in the

acute evaluation of most patients with stroke. Limitations include availability, patient cooperation, and contraindications to the procedure because of metallic foreign bodies or devices. Though their exact role in acute stroke care has yet to be defined, computed tomography angiography and magnetic resonance arteriography (MRA) may be of particular benefit in evaluating the patient with suspected carotid or vertebrobasilar artery dissection.

ED MANAGEMENT

The primary goal of acute stroke management is to reverse the clinical deficit by reestablishing cerebral blood flow, if possible. Patients who present within 3 hours of symptom onset are the most likely to benefit from intravenous recombinant tissue plasminogen activator (r-TPA, alteplase) and eligible patients should be treated (9,10). Data also support the use of intravenous r-TPA in selected patients who can be treated within 4.5 hours of symptom onset, though this indication does not have FDA approval (11).

Intravenous Thrombolytic Therapy

The American College of Emergency Physicians, American Academy of Neurology, and American Heart Association support the use of r-TPA (alteplase) in eligible patients. The NIH/NINDS Stroke Study found that r-TPA-treated stroke patients were at least 30% more likely to have minimal or no disability 3 months after the event, compared with those who received placebo (absolute increase in favorable outcome, 11% to 13%). Although treated patients had a symptomatic intracranial hemorrhage rate of 6.4% (vs. 0.6% for placebo), there was no significant difference in mortality at 3 months (17% r-TPA, 21% placebo) (12). Post hoc analyses do not support withholding therapy from any patient on the basis of suspected stroke subtype, age, clinical deficit, or CT findings of early ischemic changes.

Data also demonstrate the safety of community delivery of r-TPA in stroke. In a study of Michigan community hospitals, 557 stroke patients received intravenous r-TPA in the emergency department.

The symptomatic intracerebral hemorrhage (ICH) rate was equivalent to the NINDS study (12).

The development of treatment guidelines for stroke may improve patient selection and speed the delivery of thrombolytics to appropriate patients. The National Institutes of Health recommends a target "door-to-needle" time for eligible r-TPA patients of 60 minutes.

Table 155.3 outlines inclusion and exclusion criteria for the use of intravenous r-TPA in acute stroke. Eligible patients should be treated with 0.9 mg/kg of r-TPA (maximum dose, 90 mg), with 10% given as a bolus over 1 to 2 minutes and the remainder given over 60 minutes via infusion pump. Administration of r-TPA between 3 and 4.5 hours after stroke onset may be considered for patients meeting the additional criteria listed in Table 155.3 (11). Table 155.4 presents posttreatment blood pressure control guidelines. An algorithm for the management of suspected intracranial hemorrhage secondary to thrombolytic therapy is shown in Figure 155.1.

TABLE 155.3
Intravenous r-TPA in Ischemic Stroke: Inclusion and Exclusion Criteria

Inclusion Criteria

1. Age 18 or older
2. Clinical diagnosis of ischemic stroke
3. Time of onset well established to be <180 min before treatment would begin. *"Time of onset" of stroke is defined as that point at which a change in the baseline neurologic function occurred. If that time is not known (e.g., the patient awakens from sleep with new symptoms), the last time the patient was observed to be neurologically intact* must *be considered to be the time of onset.*

Exclusion Criteria

1. Significant head trauma in prior 3 months
2. History of prior stroke within 3 months
3. Symptoms suggestive of subarachnoid hemorrhage
4. Arterial puncture at noncompressible site in prior 7 days
5. History of prior intracranial hemorrhage
6. Intracranial neoplasm, arteriovenous malformation, or aneurysm
7. Recent intracranial or spinal surgery
8. Recent lumbar puncture (within previous 7 days)
9. Elevated blood pressure (systolic > 185 mm Hg or diastolic > 110 mm Hg)[a]
10. Blood glucose concentration < 50 mg/dL (2.7 mmol/L)
11. CT demonstrates multilobar infarction (hypodensity involving >1/3 of the cerebral hemisphere)
12. Active internal bleeding
13. Acute bleeding diathesis, including but not limited to:
14. Platelet count <100,000/mm^3
15. Heparin administered within 48 h with an abnormal activated partial thromboplastin time (aPTT)[b]
16. Current use of anticoagulant with INR >1.7 or PT >15 s[b]
17. Current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory tests (such as aPTT, INR, ECT [ecarin clotting time], TT [thrombin time], or factor Xa activity assay)

Relative Exclusion Criteria

Experience indicates under some circumstances patients may receive fibrinolytic therapy despite having relative contraindications. Consider risk to benefit carefully if any of these relative contraindications are present as well as consulting a stroke specialist.

1. Only minor or rapidly improving stroke symptoms
2. Pregnancy
3. Seizure at onset with postictal residual neurologic impairment
4. Major surgery or serious trauma within previous 14 d
5. Recent gastrointestinal or urinary tract hemorrhage (within previous 21 d)
6. Recent acute myocardial infarction (within previous 3 mos)

Additional Exclusion Criteria for Treatment between 3 and 4.5 h of onset

1. Age >80 yrs
2. Severe stroke (NIHSS >25)
3. Taking oral anticoagulant, regardless of INR
4. History of both diabetes and a prior stroke

[a]Hypertension may be treated with labetalol 10–20 mg IV over 1–2 min (may repeat × 1) or nicardipine infusion and TPA initiated if reduction to above levels occurs. More aggressive treatment to reduce blood pressure excludes the patient from treatment with TPA.

[b]In patients without a history of recent oral anticoagulants or heparin use treatment with r-TPA can be initiated before the availability of coagulation study results, but should be discontinued if either the PT is >15 s or INR >1.7 or the PTT is elevated.

TABLE 155.4
Post r-TPA Blood Pressure Management in Acute Stroke

1. Monitor BP every 15 min
2. If systolic BP is 180–230 mm Hg or diastolic BP 105–120 mm Hg, give labetalol 10 mg IV over 1–2 min followed by an infusion at a rate of 2–8 mg/min; or
3. Nicardipine 5 mg/h IV, titrate to effect by increasing/decreasing 2.5 mg/h every 5–15 min, maximum 15 mg/h
4. If blood pressure not controlled, consider sodium nitroprusside infusion

Adapted from: Jauch EC, Saver JL, Adams HP Jr, et al. Guidelines for the early management of patients with acute ischemic stroke: A guideline for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke*. 2013;44(3):870–947.

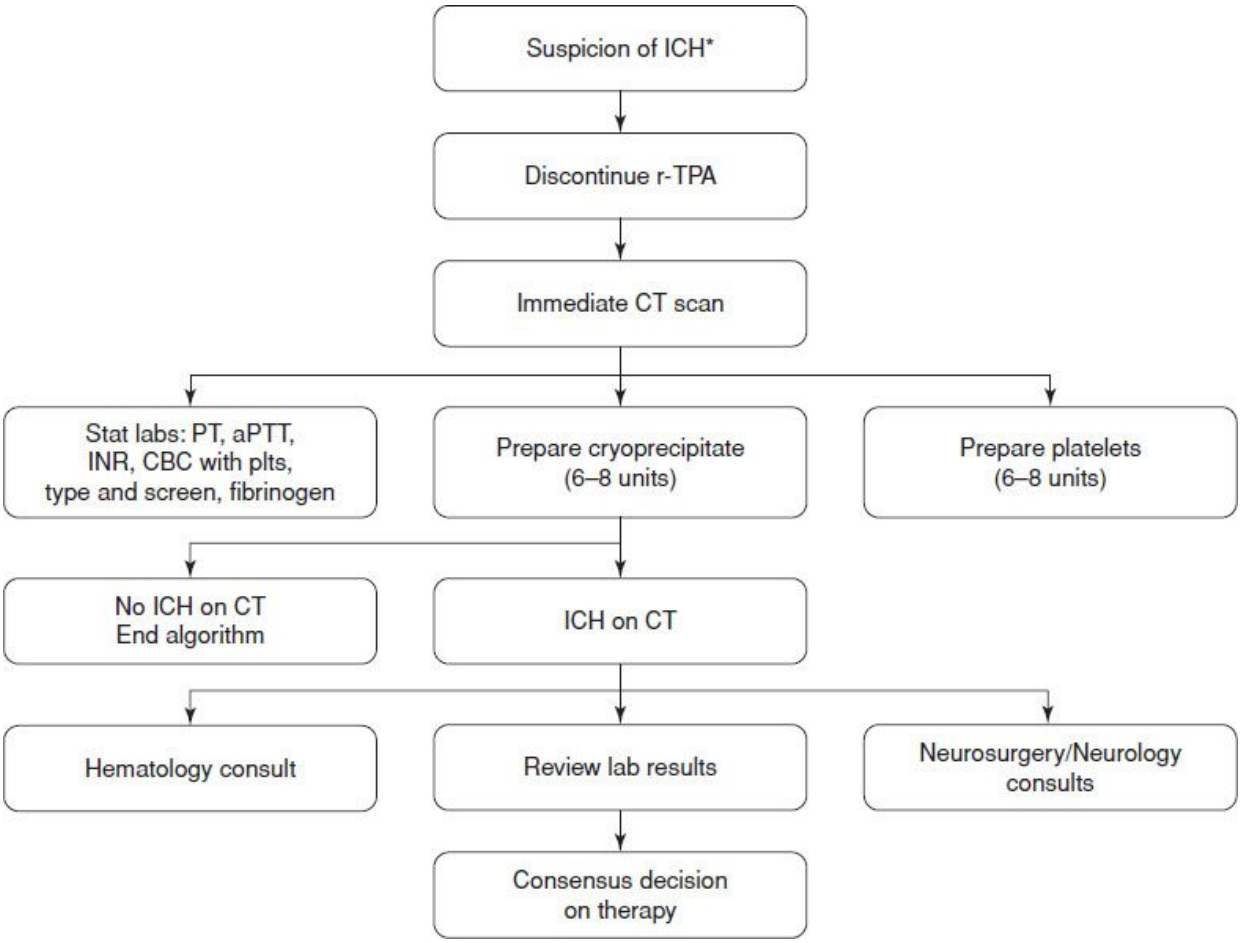

FIGURE 155.1 Management of suspected intracranial hemorrhage after r-TPA use. *Symptoms include neurologic deterioration, headache, acute hypertension, nausea, vomiting.

The development of institution-specific evaluation and treatment guidelines is recommended to identify local responsibilities concerning thrombolytic delivery and posttreatment care and disposition. A multidisciplinary approach will deliver the highest level of care in a time-critical setting.

Endovascular Therapy

Intra-arterial thrombolysis or mechanical reperfusion are potential considerations for patients who are ineligible for intravenous thrombolytic therapy (due to late presentation >4.5 hours from symptom onset or other reasons) presenting within 6 to 8 hours of

symptom onset (13,14). Their exact role, however, is unclear. Two recent trials found no clinical improvement using endovascular therapy compared to standard intravenous r-TPA alone (15,16). The use of advance neuroimaging to select stroke patients with favorable penumbral patterns for mechanical embolectomy using the Merci Retriever or Penumbra System also failed to demonstrate superiority of those devices over standard treatment (17). Technology in this area is rapidly advancing and decisions regarding endovascular treatment should be made with qualified specialists, preferably within the context of a clinical trial.

In patients who are ineligible for reperfusion strategies, no acute intervention has proven effective in improving functional outcome. The objective of treatment is then to limit infarct extension and recurrence. Current approaches to preventing or minimizing infarct extension include maintenance of adequate cardiac output to preserve cerebral blood flow, regulation of core temperature, and control of the blood glucose level. Strategies to prevent recurrent infarction focus on antiplatelet and anticoagulation therapy.

Hypertension Management

Acute elevations of blood pressure typically decline, without treatment, within a few days to prestroke levels. Because the benefit of blood pressure control is unproved, it is reasonable to avoid treating hypertension in the absence of specific indications such as thrombolytic therapy for acute stroke, AMI, hypertensive encephalopathy, arterial dissection, and hemorrhagic transformation. Although no data exist to define the point of treatment for severe isolated hypertension in stroke, there is consensus that antihypertensive agents should be withheld unless the blood pressure exceeds 220/120 mm Hg.

In stroke patients who are not eligible for r-TPA and who require antihypertensive therapy, the goal is a gradual reduction of blood pressure by about 15%. No data are available to guide selection of medications for the lowering of blood pressure in this setting. Reasonable initial agents include labetalol, 10 to 20 mg IV over 1 to 2 minutes, repeated or doubled every 10 minutes (maximum dose,

300 mg) or nicardipine, 5 mg/h IV infusion as initial dose; titrated to desired effect by increasing 2.5 mg/h every 5 minutes to maximum of 15 mg/h. For patients with DBP >140 mm Hg, consider a sodium nitroprusside infusion, 0.5 μg/kg/min IV as initial dose with continuous blood pressure monitoring and titration. The use of antihypertensive agents requires frequent neurologic checks so that treatment may be discontinued if there is neurologic deterioration (10).

Volume Management

Maintenance of intravascular volume is important in optimizing cardiac output in stroke patients. These patients are often unable to maintain adequate oral intake, and up to one-third may be significantly hypovolemic. Volume deficits should be corrected as rapidly as possible and followed by maintenance fluids. Avoidance of hypoosmolar solution is recommended to prevent exacerbation of cerebral edema. Aggressive hypervolemic therapy to increase cerebral blood flow should be avoided because it does not improve outcome and may contribute to cerebral edema. Hemodilution has also not been proven to alter stroke outcome and cannot be recommended.

Temperature Regulation

Temperature regulation of the ischemic stroke patient is often neglected in the ED. Experimentally, hypothermia has a protective effect on ischemic neurons, whereas hyperthermia may worsen damage by increasing cellular metabolic demand. Fever is not uncommon in stroke patients and should be promptly treated.

Glucose Regulation

Because the optimal glucose level after stroke is unknown, it is reasonable to treat excessive levels (possibly beginning at levels of 140 to 180 mg/dL) with insulin. Close monitoring of glucose levels with adjustment of therapy is recommended (10). Hypoglycemia should be promptly corrected.

Anticoagulation

In patients with ischemic stroke, early anticoagulation has no proven benefit and is associated with an increased risk of serious bleeding complications and hemorrhagic transformation of the infarct. No well controlled, randomized, clinical trial has demonstrated a benefit from anticoagulation even in potentially high-risk groups: Patients with intracardiac or intra-arterial thrombi, vertebrobasilar disease, or arterial dissection. Therefore, emergent anticoagulation to improve neurologic outcome or prevent early recurrent stroke is not recommended (10). Given the lack of evidence and the potential risks, consultation is recommended prior to anticoagulation initiation in stroke. All anticoagulants should be withheld for 24 hours after the use of r-TPA in acute stroke.

Antiplatelet Therapy

Antiplatelet therapy is a cornerstone of stroke management and reflects the central role of platelet activation in clot formation. The use of aspirin in patients with a previous mild stroke or TIA results in a 20% reduction in stroke risk. In patients treated within 48 hours of stroke onset with 300 mg of aspirin daily, there was a statistically significant reduction in recurrent ischemic stroke at 14 days, with no increase in risk of hemorrhagic stroke (18). Initiation of aspirin therapy (initial dose 325 mg) is recommended in patients who are not treated with thrombolytic therapy and do not have aspirin sensitivities or swallowing difficulty. The combination of clopidogrel (Plavix) and aspirin proved superior to aspirin alone in reducing the 90-day incidence of stroke (8.2% vs. 11.7%) in a Chinese study of patients with acute TIA or minor stroke (NIH stroke scale <3) (6) (Fig. 155.2). Data on non-Chinese populations is not yet available.

CRITICAL INTERVENTIONS

- Obtain an emergent CT scan.
- Initiate aspirin therapy for nonhemorrhagic ischemic strokes that are not eligible for TPA and do not have swallowing difficulties.
- Identify patients eligible for thrombolytic therapy and expedite their diagnostic evaluation and treatment.
- Correct hyperthermia.

DISPOSITION

Factors influencing disposition in the patient with ischemic stroke include infarct location, time of symptom onset, infarct size, stroke etiology, concurrent medical conditions, and social resources available to the patient. The vast majority of stroke patients are admitted to the hospital, often to a specialized unit or floor skilled in the care of patients with neurologic deficits. Cardiac monitoring is recommended to assess for atrial fibrillation and other arrhythmias.

Patients with minor, completed strokes are potential candidates for evaluation in an ED clinical decision unit. Predefined protocols for neurologic consultation, subsequent neurologic and vascular imaging, and initiation of therapy to prevent recurrent stroke in this setting speed patient care and reduce length of hospital stay.

Common Pitfalls

- Failure to perform a complete history and physical examination, particularly in uncooperative elderly patients. The history and physical examination are the basis for determining the extent of a stroke and its etiology.
- Failure to consider unusual etiologies of stroke, such as arterial dissection and emboli, in younger patients with new neurologic deficits.
- Misdiagnosis of cerebellar stroke as alcohol or drug intoxication, labyrinthitis, benign positional vertigo, or severe gastroenteritis,

and failure to obtain neurosurgical consultation.
- Failure to optimize cardiac output and to treat temperature elevations in the ED.
- Overly aggressive blood pressure management. Reduction of blood pressure may reduce cerebral blood flow and lead to extension of an ischemic stroke.
- Initiation of anticoagulation in patients with acute stroke prior to consultation.

Patients treated with r-TPA and those with impaired gag or swallowing reflexes or mental status changes should be admitted to the intensive care unit or a specialized stroke unit. Similar admission is also indicated for patients with cerebellar strokes and should be considered for patients with large hemispheric strokes who are at risk for the development of cerebral edema.

Stroke patients are often cared for in the inpatient setting without neurologic consultation. Neurologic consultation in the ED is indicated when the diagnosis is unclear or when further evaluation is required (e.g., arterial dissection, migrainous infarct, unusual hematologic conditions). Patients with cerebellar infarction should have neurosurgical consultation, because decompressive craniectomy may be lifesaving in selected patients.

HEMORRHAGIC CEREBROVASCULAR DISEASE

ICH, defined as hemorrhage directly into the brain parenchyma, affects 10% to 15% of all stroke patients. Major risk factors for intracranial hemorrhage include advanced age, hypertension, and race. Blacks have a higher incidence of ICH than do whites; other risk factors include cigarette smoking and alcohol use.

The most common site for ICH is the putamen, which accounts for 35% to 50% of all hemorrhages. Next in frequency are the subcortical white matter (30%), the cerebellum (16%), the thalamus (10% to 15%), and the pons (5% to 12%) (11). Pathologically, these are areas of the brain supplied by small arteries that are 50 to 200 μm in size.

CLINICAL PRESENTATION

The onset of ICH is usually heralded by a sudden headache, vomiting, and neurologic deficit. Many patients exhibit a decreased level of consciousness owing to ICP. ICH often occurs during activity and only rarely has its onset during sleep. In one-third of cases, clinical deficits are maximal at onset. In the remaining two-thirds, the symptoms follow a steadily progressive course over the first 30 minutes. Coma is a poor prognostic sign and is associated with larger hemorrhages and ventricular extension. Headache and vomiting are typically absent in ischemic strokes and thus are of help in identifying patients with ICH. Early seizures are uncommon in ICH involving the putamen, thalamus, and pons but may be present in up to one-third of patients with subcortical white matter ("lobar") hemorrhages. Hypertension is noted in more than 90% of patients with ICH.

The clinical deficits are related to the location and size of the hemorrhage. Putaminal hemorrhages cause a dense contralateral hemiplegia with sensory loss and homonymous hemianopia. The eyes show conjugate deviation away from the paralyzed side, which may overcome with caloric testing or doll's-eye reflex testing. Thalamic hemorrhages cause similar motor and sensory findings but may also cause conjugate downward gaze with pinpoint, unresponsive pupils. Deficits from a lobar hemorrhage depend on the size and location of the hemorrhage. Pontine hemorrhage typically causes a severe occipital headache, followed rapidly by a decreased level of consciousness; coma is present in 80% of patients. Patients may become hyperthermic and may have severe neurologic deficits. These include quadriplegia, loss of corneal reflexes, and pinpoint pupils with absent horizontal eye movements on caloric or doll's-eye reflex testing. Cerebellar hemorrhage causes extremity and truncal ataxia and an inability to walk. These symptoms are commonly accompanied by vomiting, disequilibrium, and headache. An ipsilateral gaze palsy may also be present. Patients with cerebellar hemorrhage may initially appear stable but can deteriorate rapidly to coma and death.

DIFFERENTIAL DIAGNOSIS

The presence of intracerebral blood on head CT should not automatically be ascribed to a hypertensive hemorrhage. Various nonhypertensive causes of ICH include arteriovenous malformation, berry aneurysm, sympathomimetic drug use, intracranial tumor, use of anticoagulant and thrombolytic agents, hematologic disorders (e.g., leukemia, thrombotic thrombocytopenic purpura, hemophilia), cerebral vasculitis, and mycotic aneurysm.

ED EVALUATION

The evaluation of patients with suspected ICH is similar to that for ischemic stroke. However, patients with ICH may exhibit rapid neurologic deterioration and a decreased level of consciousness, necessitating acute airway intervention. Vital signs should be monitored closely, and frequent neurologic assessments are required. A general physical examination should be completed in addition to a rapid and thorough neurologic examination. Use of structured examination tools including the NIH Stroke Scale (Fig. 155.2) can provide easy quantification of deficits to allow serial comparisons over time and enhance communication between medical providers. The Glasgow Coma Score is a good predictor of long-term outcome.

KEY TESTING

- Additional investigations in the patient with suspected or confirmed ICH are identical to the Key Testing recommended for Ischemic Stroke.
- Laboratory data should be obtained to help identify possible contributing causes, such as coagulopathy, thrombocytopenia, or platelet dysfunction.
- Toxicologic screening is indicated for patients with atypical presentations and for younger patients without a history of hypertension.

ED MANAGEMENT

The goals of emergency care for ICH are rapid diagnosis, management of the airway, correction of coagulation deficiencies, control of ICP, and early neurosurgical consultation. Oxygen should be administered to maintain oxygen saturation as needed. Intubation is indicated for airway protection or hyperventilation to reduce ICP. Rapid sequence intubation with paralytic agents may be necessary to obtain adequate CT images in a combative patient.

Patients on warfarin should have their warfarin held, undergo replacement of vitamin K–dependent factors to correct the INR, and receive intravenous vitamin K. Prothrombin complex concentrates (PCCs) have not demonstrated improved clinical outcomes compared to traditional fresh frozen plasma (FFP) but have advantages of speed of administration, smaller volume, and reduces risk of infectious disease transmission, and are increasingly recommended for warfarin reversal. Recombinant factor VIIa can limit the extent of hematoma expansion in noncoagulopathic ICH patients but increases the risk of thromboembolic events and has no clear clinical benefit (19). It does not replace all clotting factors and is not recommended as the sole reversal agent for warfarin-associated hemorrhage (20).

Recommendations for the optimum reversal strategy of newer oral direct thrombin inhibitors and factor Xa inhibitors are problematic, as no direct antidote is available and only limited data exists on effective reversal strategies. The best data at this time suggest that PCCs might be useful. Emergent consultation with local coagulation specialists is reasonable in this rapidly changing area.

Hyperglycemia should be avoided, and maintenance of normoglycemia is recommended.

Prophylactic anticonvulsant medication should not be used, though patients with clinical seizures or evidence of seizure on EEG should be treated with antiepileptic drugs (20).

Management of hypertension in the patient with ICH is also rapidly evolving. Data from the international INTERACT2 trial demonstrated safety in targeting acute blood pressure reduction to 140 mm Hg—with a trend toward reducing death or severe disability —in patients with spontaneous ICH with elevated systolic blood pressures (21). A North American trial (ATACH II) is currently

underway. Useful antihypertensive agents in the setting of ICH include nitroprusside, esmolol, labetalol, nicardipine, enalapril, hydralazine, and nitroglycerine.

Data regarding ICP control in patients with ICH is very limited. ICH patients with a GCS score of ≤ 8, clinical evidence of herniation, or those with significant intraventricular hemorrhage or hydrocephalus might be considered for ICP monitoring and treatment. Elevations in ICP, defined as readings ≤ 20 mm Hg for 5 minutes, may present as a decreasing level of consciousness and/or neurologic deterioration. Initial management options include elevation of the head (30 degrees), osmotherapy, and hyperventilation. Osmotherapy options include mannitol (20% solution; 1 g/kg bolus) and hypertonic saline (250 cc of 7.5% saline). Target serum osmolality has been recommended to be 300 to 320 mOsm/kg, although definitive data are lacking (20).

Reduction of the pCO_2 to 30 to 35 mm Hg lowers ICP by 25% to 30% in most patients, though peak ICP reduction may be delayed up to 30 minutes after the pCO_2 is changed. Because hypocarbia causes cerebral vasoconstriction, overaggressive reduction in pCO_2 may reduce cerebral blood flow below critical values and should thus be avoided.

In general, ICP monitoring is indicated in patients whose condition is thought to be deteriorating owing to increases in ICP. Other patients may warrant ICP monitors, however, particularly those with intraventricular hemorrhage. Placement of an intraventricular catheter offers the potential for direct removal of cerebrospinal fluid and reduction of ICP.

Neurosurgical consultation should be obtained early and, if unavailable, the patient should be stabilized and transferred. The indications for hematoma evacuation depend on many factors, including patient age, hemorrhage location and size, and surgical accessibility. Patients who present initially with coma or loss of brainstem function generally do not benefit from surgical evacuation, whereas those who experience progressive deterioration after a lobar hemorrhage are often operated on. In patients with cerebellar hemorrhage, surgical evacuation as soon as possible is recommended

for patients who are deteriorating neurologically or have brainstem compression and/or hydrocephalus.

CRITICAL INTERVENTIONS

- Protect the airway.
- Correction of abnormal coagulation.
- Manage elevated ICP.
- Obtain neurosurgical consultation.

DISPOSITION

All patients with ICH should be admitted for close observation and monitoring. Typically, intensive care unit monitoring is required. If neurosurgical treatment capabilities are not available locally, arrangements should be made to transfer the patient.

Common Pitfalls

- Failure to diagnose cerebellar hemorrhage. Patients may be misdiagnosed with acute viral syndrome, labyrinthitis, or intoxication. Surgical intervention may be lifesaving.
- Delay in transport. Patients with ICH require early neurosurgical consultation and should be transported to an appropriate facility if immediate neurosurgical attention is not otherwise available.

CHAPTER 156

Seizures

Andy Jagoda

Seizures are both a primary problem and a result of an underlying disorder. They account for an estimated 1% to 2% of emergency department (ED) visits. Two to 4 million Americans have epilepsy, a condition of recurrent unprovoked seizures.

Seizures result from excessive and disorderly neuronal discharge in the cerebral cortex. Epilepsy is a condition of unprovoked seizures, whereas an underlying pathologic process provokes other seizures. The clinical manifestations of a seizure reflect the area of the brain in which neurons are discharging abnormally. Seizure discharges and symptoms may be focal or may be generalized to both hemispheres. The clinical spectrum of seizures includes focal or generalized motor activity, altered mental status, sensory or psychic experiences, or autonomic disturbances.

Ictus refers to the period during which a seizure occurs. An aura, or "warning," represents the beginning of a partial seizure, which can remain focal or can spread into a generalized event; a corollary is that patients with a primary generalized seizure (affecting both hemispheres without a focus) disorder do not have an aura. The period after a seizure but before the patient returns to baseline mental status is called the postictal period.

An acute symptomatic seizure, also referred to as a provoked seizure, is a seizure that occurs within 7 days of an acute CNS or systemic event, for example, stroke, hypoglycemia, head trauma. A remote symptomatic seizure is a seizure that occurs more than 7 days from an inciting event.

Status epilepticus (SE) is broadly defined as prolonged seizure activity with a high morbidity and mortality. Time definitions are changing for SE: It had been defined as seizures that last >30 minutes or in which there are recurrent seizures without a return to baseline mental status between events. Currently some researchers define SE as a seizure that lasts 5 to 10 minutes or two seizures without full recovery between them (1,2). The longer a seizure lasts the more neuron injury occurs, and the more difficult it is to stop the seizure activity. There are a projected 125,000 to 200,000 cases of SE each year in the United States, with an overall mortality of 22%. There is a bimodal distribution of cases, with the highest incidence occurring in the first year of life and after the age of 60 years. More than one-half of patients presenting to the ED in SE have no prior seizure history.

CLINICAL PRESENTATION

The classification of seizures (Table 156.1) is based on the behavioral, electrophysiologic, and clinical features of the event rather than on pathophysiologic mechanisms or anatomic localization. Seizures can be broadly divided into primary generalized seizures and partial seizures (also called focal seizures). Primary generalized seizures do not have an inciting focus but begin bilaterally in both hemispheres of the cerebral cortex. Partial seizures begin in a localized area of the brain; they may remain focal but can also spread to incorporate both hemispheres, in which case, the seizure is termed *secondary generalized.* Among the types of new onset seizures in adults, partial seizures are more common than primary generalized seizures (3).

TABLE 156.1
Classification of Seizures

Partial Seizures

A. Simple partial
   1. Motor
   2. Somatosensory
   3. Autonomic
   4. Psychic
B. Complex partial
C. Secondary generalized

Generalized Seizures

A. Nonconvulsive (absence)
B. Convulsive
   1. Tonic clonic
   2. Clonic
   3. Tonic
   4. Myoclonic
   5. Atonic

Status Epilepticus

A. Convulsive generalized
B. Convulsive focal
C. Nonconvulsive

There are six types of generalized seizures (Table 156.1); five have convulsive activity, and one has nonconvulsive activity (absence seizure). All primary generalized seizures, except myoclonic seizures, are associated with an altered level of consciousness. Generalized convulsive seizures classically begin as myoclonic jerks followed by loss of consciousness and sustained generalized skeletal muscle contractions. The seizure activity lasts 90 to 120 seconds and may be associated with urinary incontinence and tongue biting. The convulsive seizure is followed by the postictal state characterized by a brief period of confusion and somnolence. It is not possible to have a bilateral tonic–clonic event with preservation of mental status. This fact can be helpful at times in distinguishing neurogenic seizures from psychogenic seizures.

Absence seizures are primary generalized events causing an alteration in mental status without significant motor activity. Patients have short episodes of sudden immobility and a blank stare. Absence seizures are more frequent between the ages of 5 and 10 years and are infrequent after the midteens. The average duration is 10 seconds, and there is rarely a postictal period.

Partial seizures are subdivided according to associated impairment of consciousness. Simple partial seizures have brief sensory or motor manifestations with no impairment of consciousness and are categorized according to clinical presentation (Table 156.1). Partial seizures that cause an impairment of consciousness are termed

complex partial seizures. These seizures have been known as temporal lobe or psychomotor seizures and are characterized by mental and psychological symptoms including changes in effect, confusion, or hallucinations. Partial seizures that evolve to generalized seizures are associated with altered consciousness just as other generalized seizures.

When a patient arrives to the ED with a generalized seizure or postictal, it can be difficult to differentiate between a primary generalized seizure and a secondary generalized partial seizure. A careful history can elicit a preceding symptom such as an aura, focal movement abnormality, or even staring behavior leading to a diagnosis of partial seizure that has generalized. A focal finding on computed tomography (CT) scan suggests a partial seizure that has secondarily generalized.

Seizures may have harmful secondary traumatic or metabolic consequences. Seizures may result in a fall or a motor vehicle accident. The convulsive movements of a seizure may result in injury from direct trauma to head, trunk, or limbs. There is typically a period of transient apnea and hypoxia, the duration of which varies with the duration of seizure activity. There is an increase in blood pressure, serum lactate and serum glucose levels, and white blood cell (WBC) count without a left shift. Body temperature is frequently elevated. Lactic acidosis occurs within 60 seconds of a convulsive event and normalizes within 1 hour. A transient cerebrospinal fluid pleocytosis of up to 20 WBC/μL has been reported to occur in 2% to 23% of seizure patients (Table 156.2).

TABLE 156.2
Physiologic and Systemic Consequences of Convulsive Seizures

Physiologic	Systemic
Hyperthermia	Central nervous system edema
Acidosis	Pulmonary edema
Hypoglycemia/hyperglycemia	Hypertension followed by hypotension
Hypoxia	Dysrhythmias
Acidosis	Rhabdomyolysis
Leukocytosis	Disseminated intravascular coagulation
Cerebrospinal fluid pleocytosis	Fractures/dislocations

DIFFERENTIAL DIAGNOSIS

Seizure Mimics

Some nonseizure conditions can mimic seizures. Such conditions include syncope, dysrhythmia, migraine, vertigo, sleep disorders, decerebrate posturing, drug reactions, tetanus, strychnine poisoning, and psychogenic events. Other, less common, seizure mimics include narcolepsy, hyperventilation syndrome, and dystonic reactions. A detailed history and physical can usually differentiate among these conditions.

Syncope can be associated with occasional twitching movements, which can be misdiagnosed as a seizure and can be called convulsive syncope. Full tonic–clonic movements, tongue biting, and postictal amnesia have not been commonly described in convulsive syncope. When put in the context of when and where the event occurred, the length of event, and the type of movements, convulsive syncope can usually be reliably differentiated from seizure.

Migraine with an aura can be confused with nonconvulsive seizures. This is compounded by the finding that many migraine patients have abnormal electroencephalograms (EEGs). Basilar migraine can result in loss of consciousness, making the differentiation even more difficult.

Psychogenic seizures, referred to as pseudoseizures, are functional events with a clinical presentation mimicking neurogenic seizures, with no corresponding alteration in EEG activity. These events are often conversion reactions and not under the patient's conscious control. Up to 30% of patients referred to epilepsy clinics are diagnosed with psychogenic seizures with a mean delay from onset

of events to diagnosis of 7.2 years (4). Psychogenic seizures often last longer than neurogenic events, and there usually is not a postictal period. Patients can often recall events during the seizure, have not been incontinent, and do not incur physical injury. Psychogenic seizures are classically manifested by forward-thrusting pelvic movements and head turning from side to side (4). Several maneuvers and tests are useful in diagnosing psychogenic seizures. These patients often avoid or resist noxious stimuli. These patients may display gaze aversion and look away from an examiner, regardless of position. On laboratory testing, psychogenic seizure patients do not have a metabolic acidosis, which is nearly universal with generalized convulsive seizures. Though not helpful in the ED setting, there is not a postictal increase in serum prolactin levels.

Seizure Etiologies

Emergency physicians encounter a number of clinical scenarios involving both acute and remote symptomatic seizures. The medical causes of new seizures may be the result of acute or progressive neurologic insults or systemic stressors, and the evaluation of the patient with seizures must always look for those potentially reversible or treatable causes (Table 156.3). The two most commonly identified etiologic antecedents to seizures are neurologic injury from birth (8%) and cerebrovascular disease (11%) (3). Other identified etiologies of secondary seizures include trauma (5.5%), neoplasm (4%), degenerative disease (3.5%), and infection (2.5%). In the elderly, the cause of seizure is more likely to be vascular (stroke), degenerative, or neoplastic than the causes in the young (5).

TABLE 156.3
Etiology of Seizures

I. Idiopathic
II. Structural
    A. Degenerative disease (e.g., multiple sclerosis, tuberous sclerosis)
    B. Neoplasm
    C. Scar from birth trauma, other trauma, anoxic damage
III. Infection: Bacterial, Viral, Parasitic, Syphilitic
    A. Meningitis
    B. Encephalitis
    C. Abscess
IV. Metabolic
    A. Hypoglycemia
    B. Hyperosmolar states
    C. Hyponatremia
    D. Hypocalcemia
    E. Hypomagnesemia
    F. Hypoxia
    G. Uremia
    H. Thyroid disease
    I. Nutritional deficiency
V. Toxin
    A. Drug withdrawal
        1. Alcohol
        2. Benzodiazepine
        3. Antiepileptic drug
    B. Drug overdose
        1. Isoniazid
        2. Tricyclic antidepressant
        3. Anticholinergics, including antihistamines
        4. Salicylates
        5. Theophylline
        6. γ-hydroxybutyrate
        7. Cocaine and related stimulants
VI. Vascular
    A. Subdural hematoma
    B. Epidural hematoma
    C. Intraparenchymal hemorrhage
    D. Stroke
    E. Subarachnoid hemorrhage
    F. Arteriovenous malformation
VII. Eclampsia

Metabolic and toxin-related etiologies must always be considered in the differential diagnosis and are often the most reversible. Hypoglycemia is the most common metabolic cause of seizures; hyponatremia, hypocalcemia, and hypomagnesemia are much less common (6). Interestingly, the metabolic encephalopathies, such as nonketotic hyperglycemia and uremia, can cause both focal and generalized seizures. Alcohol is the toxin most commonly associated with seizures, followed by tricyclic antidepressants, anticholinergics, cocaine, amphetamines, antihistamines, theophylline, and isoniazid. Drug withdrawal, including noncompliance with anticonvulsant medications in patients with a known seizure disorder, is a leading cause of recurrent seizures.

Acute central nervous system (CNS) infections are responsible for 4% to 12% of acute isolated seizures and up to 28% of cases of refractory SE.

A number of physiologic and psychological stressors can activate seizure disorders. These stressors include fatigue, sleep deprivation, hyperventilation, photic stimulation, emotional stress, and menstruation. In rare cases, seizures can be triggered by colors, objects, music, and voices. Pregnancy can also result in the onset of a seizure disorder, which is separate from eclamptic seizures.

ED EVALUATION

History and Physical Examination

The history must include a description of the event and an indication of the frequency, pattern, and duration of recent or previous seizures. Every attempt should be made to interview observers and emergency medical services (EMS) to obtain a clear description of the seizure to avoid misdiagnosing nonseizure events. One should ask the patient or EMS personnel about incontinence, loss of consciousness, and injury and determine whether there was an aura or a postictal period. Inciting factors such as medication noncompliance, infection, pregnancy, sleep deprivation, alcohol use, or other drug or medication use should be identified. A history of head trauma,

headaches, diabetes, cancer, cerebrovascular disease, electrolyte imbalances, or infections can prove vital to making a diagnosis.

The physical examination begins with the vital signs, which can provide important red flags of underlying pathology. Signs of trauma should be sought, and a careful neurologic examination performed. Both unilateral and bilateral pupillary dilation as a result of seizure has been reported. Postictal patients often have hyperreflexia, upgoing toes, evidence of incontinence, or a tongue laceration. A focal deficit can represent a metabolic derangement such as hypoglycemia, an old or a new CNS lesion, or a Todd paralysis secondary to the seizure. Todd paralysis can be manifested as either a motor or a sensory deficit. Although it typically resolves within hours of seizure, neuroimaging may be necessary to differentiate a Todd paralysis from other causes of acute focal neurologic dysfunction.

Postictal confusion is common but almost always resolves in a few hours. Other causes of altered mental status must be strongly considered in patients whose mental status remains impaired or when family or friends note an abnormally longer than normal postictal phase or unusual behavior manifestations. It is estimated that approximately 15% of patients treated for convulsive SE continue to be in nonconvulsive status after their motor activity is controlled; this unrecognized status may be a factor in the high mortality associated with SE and suggests the need for EEG monitoring if there is a prolonged “postictal” period (7). Causes of altered mental status in patients who have had a seizure are listed in Table 156.4.

TABLE 156.4
Causes of Altered Mental Status in Patients Who Have Had a Seizure

Postictal state
Persistent nonconvulsive seizures
Metabolic abnormality
Hyperosmolar state
Central nervous system infection
Central nervous system vascular event
Drug effect
Psychiatric dysfunction

Laboratory Testing

Laboratory testing in postictal patients often demonstrates a metabolic acidosis or an elevated serum–creatine phosphokinase level. These findings can be helpful and should be sought, but, unfortunately, they are time and patient dependent and their absence does not rule out the possibility that a seizure occurred.

Of all laboratory tests, serum glucose determination followed by a serum sodium determination has been found to be the most valuable in diagnosing an unsuspected etiology of seizure (8). The decision to measure other electrolytes, creatinine, blood urea nitrogen, calcium, and magnesium is based on the individual patient assessment; generally, these tests are of limited value in patients with no underlying medical problems who have returned to baseline. An arterial blood gas analysis is indicated when hypoxia or an underlying acidosis is suspected. A pregnancy test should be obtained in all women of childbearing age (6). Serum antiepileptic drug (AED) levels should be checked in patients taking such medications and in those who have had a seizure or when a history cannot be obtained (Table 156.5). Such therapeutic ranges are available for phenytoin, carbamazepine, valproate, and phenobarbital. Serum levels of most of the newer AEDs cannot be measured rapidly in most hospitals.

TABLE 156.5
Drugs Used in the Treatment of Epilepsy

Drug	Trade Name	Route	Seizure Type	Loading Dose (mg/kg)	Daily Dose for Adults (mg)	Therapeutic Range (μg/mL)
Phenytoin	Dilantin	PO, IV	P, GC	20	300–400	10–20
Fosphenytoin	Cerebyx	IV, IM	P, GC	20	—	10–20
Carbamazepine[a]	Tegretol	PO	P, GC	—	800–1,600	6–12
Valproate[b]	Depakene	PO	All	—	1,000–3,000	50–120
Divalproex sodium	Depakote	PO	All	—	1,000–4,800	50–120
	Depacon	IV	All	10–20	—	50–120
Phenobarbital		PO, IV, IM	P, GC	10–20	90–150	15–35
Levetiracetam	Keppra	PO, IV	P, GC	—	500–1500	
Primidone	Mysoline	PO	P, GC	—	750–1,250	6–12
Clonazepam	Klonopin	PO	A, M	—	1.5–20	0.02–0.08
Ethosuximide[c]	Zarontin	PO	A	—	750–1,250	40–100
Lamotrigine	Lamictal	PO	All	—	200–600	—
Felbamate[d]	Felbatol	PO	P, GC	—	1,800–4,800	—
Gabapentin[e]	Neurontin	PO	P, GC	—	900–3,600	—
Topiramate	Topamax	PO	P, GC	—	200–600	—
Tiagabine		PO	P, GC	—	32–48	—
Diazepam[f]	Diastat	Rectal	All	0.2–0.5	—	—

PO, orally; IV, intravenous; P, partial seizure; GC, generalized seizure; IM, intramuscular; A, absence seizure; M, myoclonic seizure.
[a]Drug of choice for partial seizures, with or without secondary generalization.
[b]Drug of choice for primary generalized tonic–clonic seizures.
[c]Drug of choice for absence seizures.
[d]Associated with aplastic anemia in 1 in 5,000 patients; hepatic failure in 1 in 30,000.
[e]Only anticonvulsant that is renally metabolized; recommended in patients with multiple medical problems.
[f]Used primarily in children to control clusters of breakthrough seizures.

Alcohol is by far the most common drug of abuse associated with seizures, followed by cocaine. Serum alcohol, salicylate, lithium, and theophylline levels and urine drug–screening tests should be ordered based on clinical suspicion. Since patients with epilepsy can have other medical problems (e.g., depression), other possibilities (e.g., tricyclic overdose) should not be overlooked and an electrocardiogram (ECG) considered.

Patients who have had a seizure but who are not immunocompromised and who do not have an abnormal mental status, fever, or meningeal signs do not require a lumbar puncture as part of their ED evaluation. However, seizures, especially SE, are associated with hyperthermia, leukocytosis, and altered mental status, thus often forcing consideration of encephalitis. It is also important to note that, as mentioned previously, seizures can cause cerebrospinal fluid pleocytosis, further confusing the issue occasionally. It is recommended that antibiotics and/or antivirals, once started, be continued until cerebrospinal fluid culture results are available.

Neuroimaging and Electroencephalography

CT scanning of the head is indicated in the ED when an acute intracranial event, such as subdural or subarachnoid hemorrhage, is suspected. Patients with acute trauma, a past history of malignancy, or with an abnormal neurologic examination are most likely to have an abnormal imaging study. Special populations, including immunocompromised hosts, the elderly, and immigrants from countries where cysticercosis is endemic are candidates for neuroimaging.

All patients who have had a first-time seizure will need an imaging study but not necessarily an emergent CT scan obtained during the ED stay. If the patient has a normal mental status and neurologic examination and is judged to be reliable for follow-up, it is reasonable, after consultation with a neurologist, to arrange for outpatient magnetic resonance imaging (MRI). MRI is superior to CT scanning in identifying structural epileptogenic abnormalities (9).

EEG monitoring is not a standard practice in the ED, yet there are clear indications for its use on an emergent basis (6). Any patient with altered mental status in whom nonconvulsive SE is suspected requires an emergent EEG. An emergent EEG is also indicated in patients with refractory SE who have been managed with paralysis or intravenous (IV) agents.

Additional laboratory and radiographic testing may be indicated to identify underlying complicating factors, such as cardiac dysrhythmia, urinary tract infection, sepsis, or pulmonary disease.

KEY TESTING

- Serum glucose
- Serum AED levels
- Electrolytes, creatinine, blood urea nitrogen, calcium, and magnesium (limited value in patients who have returned to baseline state)
- Urine/serum drug screen if suspected overdose
- CT or MRI of brain if suspected intracranial event. First-time seizure may have imaging in ED or as outpatient.

ED MANAGEMENT

Prehospital Concerns

In most cases, prehospital personnel will arrive at least 5 minutes after the onset of seizure activity, so patients who are still seizing on EMS arrival are best managed as presumed SE. If a patient is found convulsing or remains confused or unresponsive, the patient's blood sugar should be measured, or, if this test is not available, dextrose (D_{50} or D_{25} in children) should be administered. A randomized, double-blind out-of-hospital trial comparing IV lorazepam, diazepam, and placebo demonstrated benefit and safety of paramedic administered benzodiazepines in the management of SE in the field (10).

When IV access is not immediately available, rectal diazepam is an option, especially in children. Many parents of children with epilepsy have rectal diazepam on hand to be given, should their child have a seizure. Intramuscular (IM) injection of midazolam is also an option when IV access has not been established. A randomized double-blind noninferiority trial demonstrated that IM midazolam is as least as safe and effective as IV lorazepam for children and adults (11).

Patients with a known seizure disorder who experience a typical event and are asymptomatic afterward do not necessarily require transport to the hospital, if they have the capacity to refuse transport. Prehospital personnel should advise these patients to contact their primary care provider as soon as possible.

First-Time Seizures

Patients who have had a single, unprovoked seizure have about a 35% risk of recurrence within the next 5 years; the risk of recurrences increases to approximately 75% after two or three seizures (12). When a cause of the seizure is identified, management is based on the underlying pathology. When no cause can be identified, a risk–benefit analysis regarding initiation of antiepileptic therapy must be performed. There are significant psychological and social consequences of a diagnosis of epilepsy (i.e., individual state limitations on driving cars), as well as potential dangers from the

chronic use of antiepileptic medications. Thus, one must be cautious when labeling patients as epileptic and instituting treatment from the ED.

For most first-time seizures, if a head CT was not indicated or if one is done that is negative, the patient can be discharged with very close follow-up by a primary care physician or neurologist (6). If such follow-up cannot be assured, a neurologist should ideally see the patient prior to discharge.

If there is a structural cause noted on CT scan that does not need emergent intervention—such as calcification suggestive of cysticercosis or a remote ischemic lesion—initiation of antiepileptic medications (AED) should be considered in consultation with a neurologist. Similarly, in the case of a patient who has had prior seizures but is not on any medications, an AED should be considered.

The choice of drug is based upon the type of seizure and the ease of achieving therapeutic serum levels. First-line medications that are effective for both primary generalized seizures and partial seizures with or without secondary generalization are carbamazepine, phenytoin, and valproate. Phenytoins and valproate are available for IV loading while oral carbamazepine may take days to reach therapeutic levels.

IV phenytoin loading, 15 to 20 mg/kg, can be accomplished quickly and leads to therapeutic blood levels within 1 hour of the infusion's completion. IV phenytoin has a pH ~2, and loading can be associated with local site irritation and even necrosis if extravasation occurs. Confusion, ataxia, and hypotension—caused primarily by the diluent propylene glycol—are dose- and rate-related effects. Infusions should not be run faster than 50 mg/min in adults. Fosphenytoin is a water-soluble disodium phosphate ester of phenytoin, which does not need a propylene glycol vehicle and has a more physiologic pH than does phenytoin. Fosphenytoin has fewer side effects than phenytoin, though too rapid an infusion can still cause hypotension, ataxia, and confusion. Fosphenytoin is measured in phenytoin equivalents (PE); its dosing is the same 20 mg (PE) as phenytoin though it can be given at up to 150 mg (PE)/min. Fosphenytoin can also be given safely by the IM route, with 100% bioavailability and therapeutic

serum levels within 1 hour of a loading dose, although this requires a large volume IM injection 10 mL/500 PE. Oral phenytoin loading is another option, although it takes up to 6 hours for serum therapeutic levels to be reached (6). A daily maintenance dose of 300 mg can be given at bedtime, although, in some patients, divided dosing can provide better seizure control by minimizing variations in the blood level.

Recurrence of Seizures in Patients with Known Seizure Disorder

Noncompliance with anticonvulsant medication is, by far, the most common cause of seizure recurrence in a patient with a known seizure disorder. A patient who has been on phenytoin, but has a subtherapeutic level, should be given supplemental IV phenytoin or fosphenytoin to raise serum levels into the therapeutic range. IM fosphenytoin is another option that eliminates the need for infusion pumps and cardiac monitoring. The patient can then be discharged with instructions to resume oral dosing within 12 hours. Likewise, patients with subtherapeutic valproic acid levels can be supplemented with IV valproic acid administered at 20 mg/min and discharged on their oral regimen. Levetiracetam is also available in an IV formulation; however, because serum drug levels are not readily available, dosing augmentation must be done empirically.

Patients who have seizures despite therapeutic anticonvulsant levels must be evaluated carefully for precipitating factors such as infection, new anatomic lesions, or new medications. Decisions to increase the drug dose should be made only after communication with the patient's primary care physician. A second anticonvulsant is generally only added once a patient has failed monotherapy taken to maximum doses.

The evaluation of pregnant patients with new onset seizures should follow the same principle as in other patients. However, if no etiology is identified, anticonvulsants should be withheld, pending a neurology consult. Eclampsia is an additional consideration in

patients at more than 20 weeks' gestation (see Chapter 140, Hypertensive Disorders of Pregnancy).

Noncompliance and sleep deprivation are the two most common causes of seizure recurrence in pregnant patients with epilepsy (13). Active seizures should be treated pharmacologically, just as in the nonpregnant patient, because the risks to the fetus of seizure-related hypoxia and acidosis are greater than the potential teratogenicity of anticonvulsant medications. Phenytoin and phenobarbital have similar teratogenetic profiles; carbamazepine is probably the safest of the anticonvulsants to use in pregnancy. Beyond 24 weeks' gestation, fetal monitoring should be provided during and after a seizure.

Alcohol-Related Seizures

Alcohol-related seizures deserve special mention because alcohol use is frequently involved in patients presenting to EDs with seizures. Alcohol-withdrawal seizures classically occur 6 to 48 hours after a significant reduction in the serum alcohol level, but they have also been associated with rising blood ethanol levels in some patients. Alcohol-related seizures are temporally associated with alcohol use but are not necessarily solely the result of the alcohol. Alcoholics are susceptible to cerebrovascular insults, trauma, metabolic disorders, and infections and are thus at increased risk for seizures. Management of the alcoholic who has had a seizure focuses on determining whether the event was a withdrawal seizure or because of another etiology. Patients with a first-time alcohol-related seizure should be evaluated fully in the same manner as any other patient.

The diagnosis of alcohol-withdrawal seizures is based on the history, and the clinician must always consider the possibility that another etiology is responsible. There is no good evidence to support the use of phenytoin either acutely or chronically in the management of alcohol-withdrawal seizures. Benzodiazepines alone are sufficient to prevent successive withdrawal seizures in the acute setting. Patients who have had one alcohol-withdrawal seizure should be treated with lorazepam 2 mg IV. Following this, if the patients have been observed to remain seizure-free and at baseline mental status

for 6 hours with no evidence of withdrawal, they can be discharged if a suitable environment is available (14).

Psychogenic Seizures

Psychogenic seizures should be suspected in patients who are refractory to anticonvulsants and whose clinical presentation is atypical. The diagnosis is suspected particularly when a convulsing patient does not have a metabolic acidosis, and it can be confirmed, when possible, by demonstrating that an abnormal EEG does not accompany the clinical convulsion. Management of psychogenic seizures is dependent on making the correct diagnosis; although this sounds obvious, the anxiety associated with evaluating a convulsing patient often leads to the initiation of pharmacologic interventions before an adequate assessment is performed (15). The key to management is avoiding iatrogenic harm by aggressive pharmacologic interventions or supportive measures such as intubation. Long-term management usually involves a comprehensive evaluation in an epilepsy monitoring unit, with a coordinated approach involving both an epileptologist and a psychiatrist.

Status Epilepticus

The management of convulsive SE involves expedited and simultaneous maintenance of the patient's airway, breathing, and circulation; diagnostic testing; and pharmacologic intervention (Fig. 156.1). The definition of SE has changed in recent years to reflect the importance of rapid therapeutic intervention. Many researchers consider 5 minutes of continuous seizure activity to be SE. The term "impending status" has been suggested for any seizure lasting >5 minutes because videotape studies show that the mean duration of seizures is 1 minute $\pm$ 12 seconds. This average would make a seizure of 5 minutes duration "18 to 20 standard deviations away from the norm of a single seizure, indicating that something distinctly unusual and severe is happening" (16).

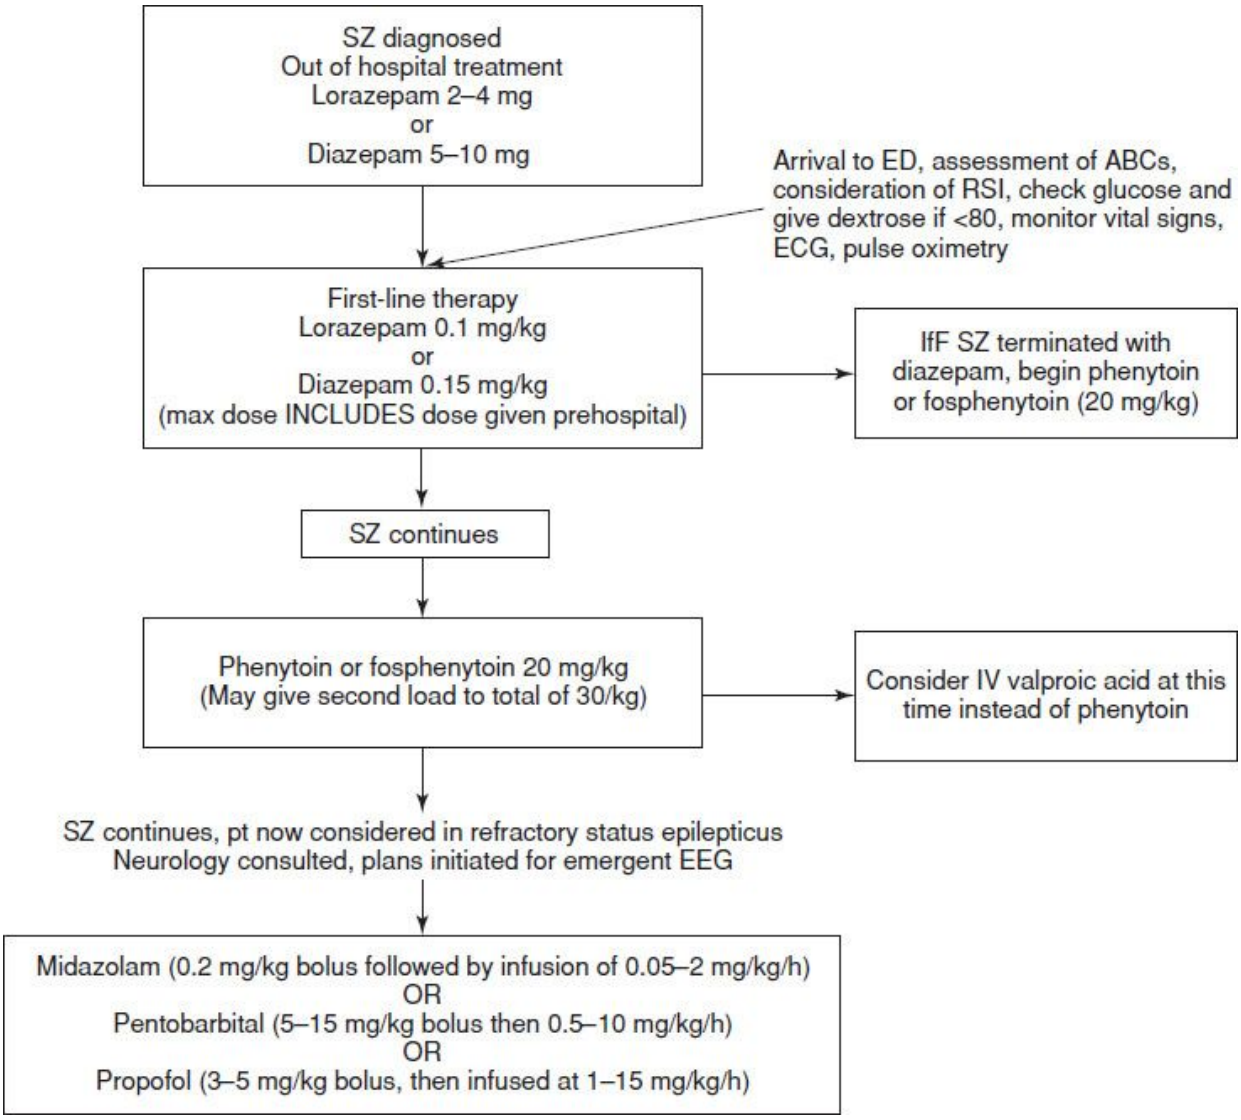

FIGURE 156.1 Approach to patient in status epilepticus. (Modified from Shearer P, Park D. Seizures and status epilepticus. *Ann Emerg Med.* 2002;39:190–192.)

SE occurs more frequently in patients with an underlying neurologic insult, either old or new, and most patients do not have a prior history of epilepsy. A population-based study reported the causes of SE as low AED levels in patients with known seizures (34%), remote symptomatic causes (24%), cerebrovascular accidents (22%), anoxia or hypoxia (~0%), metabolic causes (~0%), and alcohol and drug withdrawal (~0%) (17). Morbidity and mortality in SE is related to the etiology, duration, and systemic consequences

of the inciting event and the seizure. First-line agents for SE are the benzodiazepines (midazolam, lorazepam, or diazepam). IV phenytoin, fosphenytoin, valproic acid, and possibly levetiracetam are second-line agents. Patients who continue to seize despite aggressive use of these agents are considered to be in refractory SE and require treatment with IV anesthetic dose of midazolam, propofol, or pentobarbital. Refractory SE almost always indicates the presence of an underlying CNS disorder (18).

Airway support needs to be aggressive with continuous pulse oximetry. Patients should be intubated at any sign of hypoxia or loss of protective gag reflex. IV access should be secured using a nondextrose-containing solution because phenytoin precipitates if it is inadvertently administered with dextrose (dextrose will not precipitate fosphenytoin). Fluids should be run at keep-open rates unless the patient is hypotensive, because SE can be associated with both cerebral and pulmonary edema. When patients are intubated, short-acting paralytic agents should be used as continued motor activity, will be masked by long-acting agents lulling a clinician into a false sense of security. If prolonged paralysis is needed to carry out a procedure, a bedside EEG should be arranged.

The blood glucose level should be checked immediately by bedside testing. Blood should be tested for electrolytes, magnesium, phosphate, calcium, liver and renal function, hematocrit, WBC count, platelet count, AED levels, toxic drug screen (particularly salicylates), and alcohol. The urine should be checked for evidence of rhabdomyolysis, and a pregnancy test should be done on all women of childbearing age. The family and EMS should be questioned about the possibility of isoniazid or other drug overdose.

Patients in SE should be placed on a cardiac monitor, and an ECG should be done. A nasogastric tube should be inserted to prevent gastric distention, and a Foley catheter should be placed to help monitor volume status. A head CT scan should be done at some point in all patients. Consideration should be given to performing a lumbar puncture, if no source of the seizure activity is found.

The pharmacologic management of SE begins while the patient is being stabilized and diagnostic testing is being performed.

Hypoglycemia is treated immediately with thiamine and dextrose. Antibiotics should be given very early in the management of any patient in whom meningitis, encephalitis, or sepsis is suspected.

The benzodiazepines diazepam and lorazepam are considered the first-line drugs in the management of SE. Lorazepam (0.1 mg/kg IV, up to 10 mg) or diazepam (0.15 mg/kg IV, up to 20 mg) will stop seizures in the majority of cases. Both drugs are efficacious, but lorazepam is preferred because its anticonvulsant action lasts up to 12 hours. Diazepam has a greater volume of distribution, and, although it rapidly enters the CNS, it quickly redistributes and the CNS effect may only last 20 minutes. Consequently, if lorazepam terminates the seizure activity, no additional anticonvulsant needs to be immediately given. However, a long-lasting anticonvulsant such as phenytoin must be added when diazepam is used, or the patient will be at higher risk of seizure recurrence. The Veterans Affairs (VA) Cooperative Study compared four IV treatment regimens for convulsive SE: Diazepam followed by phenytoin, lorazepam alone, phenytoin alone, and phenobarbital alone. This well-designed, randomized, double-blind study found no outcome difference between the four treatments, although lorazepam was more effective when compared directly with phenytoin alone. The authors recommended lorazepam as the first-line agent in generalized convulsive status (2).

When seizures persist despite a full loading dose of a benzodiazepine, either valproic acid (20 mg/kg over 5 to 20 minutes), or a phenytoin is recommended (20 mg/kg of phenytoin or fosphenytoin equivalents at a rate of 50 mg/min or 150 mg/min, respectively). There is a growing body of literature supporting the early use of valproic acid instead of a phenytoin due to its efficacy and its favorable side effect profile (19,20). There is some, but limited, evidence to support IV levetiracetam as a second-line agent in treating SE. Unlike most of the agents used in treating status, levetiracetam has no hepatic metabolism, is renally excreted, and can be rapidly loaded making it an attractive agent in select cases (21).

SE that does not terminate after a benzodiazepine and a second-line agent is usually the result of a significant underlying CNS lesion.

The patient is considered to be in refractory SE and should be treated with anesthetic doses of midazolam, pentobarbital, or propofol. Studies have not shown one drug to be better than the others (22). The choice of drug for refractory SE is made on the basis of accessibility, familiarity with use, the potential role of side effects of each drug, and consideration of the preference of the admitting neurocritical care service. Underdosing and delay in starting any drug are the main pitfalls.

Midazolam is given as a loading dose of 0.2 mg/kg and is followed by an infusion of 0.05 to 2 mg/kg/h (23). Propofol provides almost immediate suppression of seizure activity after a bolus infusion (24). It is rapidly metabolized and can be titrated easily. Propofol is given as a bolus of 3 to 5 mg/kg followed by an infusion at 1 to 15 mg/kg/h. The propofol infusion syndrome of hypotension, lipidemia, rhabdomyolysis, and metabolic acidosis limits the prolonged infusion of propofol in both adults and children (25). Pentobarbital is given as 5 to 15 mg/kg at 25 mg/min, followed by 0.5 to 10 mg/kg/h as an infusion (26). Besides requiring ventilatory support, these patients are at significant risk for hypotension and therefore require hemodynamic monitoring. Hypotension should be treated with fluids and vasopressors as needed. EEG monitoring should be instituted to evaluate for continued seizure activity (27). Pentobarbital has the longest duration of action of the three agents, making it more difficult to remove when evaluating seizure suppression (28).

Many other IV and inhalational drugs have been tried in the management of refractory SE, but no controlled trials support their use (29). These drugs include inhalational anesthetics, continuous infusions of ketamine, IV lidocaine, and rectal chloral hydrate. Current recommendations would support use of these drugs only if all other measures fail.

Subtle Status Epilepticus

Subtle status occurs when the clinical manifestations of convulsive SE diminish and become less overt but the condition persists; mortality is very high in this group especially if it goes unrecognized.

Continuous EEG monitoring should thus be considered in all SE patients (2).

Nonconvulsive Status Epilepticus

Nonconvulsive SE presents as altered mental status ranging from a mild behavioral alteration noticeable only to family or friends to frank coma (30–32). Other manifestations may include speech arrest, cognitive deficits, delusions, paranoia, hallucinations, or psychosis. Because, by definition, there is rarely a significant motor component, the diagnosis is often missed, and there are many case reports of these patients initially being diagnosed with a psychiatric illness. Nonconvulsive SE has been reported in every age group, can be the initial presentation of a seizure disorder, and has been reported to last as long as 8 weeks.

The diagnosis should be suspected in patients with a seizure history who present with a prolonged postictal period or an unusual behavior pattern. Nonconvulsive SE should also be considered in patients without a seizure history who present with altered mental status of undetermined etiology. The diagnosis is made by EEG. Treatment is the same as for convulsive SE, beginning with lorazepam, 2 mg/min, until the EEG normalizes or a total of 10 mg is administered. This treatment should be followed by phenytoin loading, although it is questionable whether phenytoin is effective in absence status.

CRITICAL INTERVENTIONS

- Check a rapid glucose in patients with seizures or refractory SE.
- Protect actively seizing patients from injury.
- Administer rapid, aggressive benzodiazepine therapy for SE.
- Provide aggressive airway support for patients in SE, and intubate if there are signs of hypoxia or a loss of protective gag reflex.
- Establish a departmental protocol for management of SE.

DISPOSITION

The disposition of patients who have had a seizure depends on the etiology of the event and, often, on the socioeconomic environment to which the patient will return (33). Of prime importance is communication with the primary care provider who will be responsible for following up on the patient's diagnostic tests and medications.

Hospital admission should be considered when the cause of a seizure is unclear, when seizure recurrence has not been controlled, when the seizure is secondary to a treatable underlying illness, or when there is concern that the patient will not receive timely outpatient evaluation. All patients who have been in SE should be admitted, usually to an intensive care setting.

Common Pitfalls

- Improper infusion of phenytoin
- Assumption that altered mental status is because of a postictal state and failure to consider other possible etiologies such as subtle status or nonconvulsive status
- Failure to have and to activate an SE protocol

CHAPTER 157

Transient Global Amnesia

Richard M. Kaplan and Michael S. Joo

Transient global amnesia (TGA) is a distinct clinical entity characterized by abrupt transient memory loss regarding recent events, along with an inability to form new memories and retain new information. TGA has been reported to have a frequency of 5 to 32 episodes per 100,000 people annually (1–3). TGA may be due to transient ischemia of the vertebrobasilar and posterior cerebral circulation with medial temporal lobe dysfunction. Other possible explanations for TGA include spreading cortical depression (possibly related to migraine) or jugular valve incompetence with retrograde transmission of high venous pressures to the cerebral venous system. Patients without jugular vein incompetence may have vascular causes other than congestion (4–9). Current research has investigated the role of the hippocampal CA1 neuron which may be critical as a relay in the hippocampal-parietal network. The CA1 neuron is vulnerable to metabolic and oxidative stress, and may be involved in impairment of memory formation (10).

CLINICAL PRESENTATION

TGA may last from less than 1 hour to 24 hours. Melo (11) reported that 16 of 103 (16%) of TGA patients sustained an episode that lasted for 1 hour or less. Most episodes last from 1 to 10 hours. TGA seems to occur mainly in the morning, and the average duration is about 6 hours (3,7,8,12). Patients are usually older than 50 years of age and are disoriented to time and place, but not to self. Phrases and questions are commonly repeated, and patients have difficulty

making sense of their immediate circumstances. The patient remains attentive, follows commands, and may be able to perform simple cognitive tests, but the responses are forgotten moments later. Motor skills, speech, language, personality, and judgment remain intact. Upon recovery, the patient has complete amnesia to the events that occurred during the TGA episode (1,7,8,13).

It is imperative to obtain an accurate history regarding the specific symptoms. TGA may be associated with emotional or stressful events, sexual activity, physical exertion, exposure to pain or extremes in temperature, or medical procedures (3,5,8,11,12). If a patient's disorientation causes anxiety, this, in turn, may lead to hyperventilation, palpitation, dizziness, nausea, presyncope, paresthesias, or a choking sensation (8).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TGA includes psychogenic amnesia, complex partial seizures, central nervous system (CNS) infarction, tumor or bleed, cerebrovascular insufficiency of the posterior circulation, migraine, toxin or drug effect, head injury, metabolic abnormality, or high altitudes. Stressful events and anxiety disorders may be associated with an acute onset of psychogenic or hysterical amnesia. Unlike complex partial seizures, TGA usually lasts for hours, and patients do not experience a warning, aura, postictal symptoms, or incontinence. When electroencephalographic (EEG) testing is performed during a TGA episode, brain wave slowing without epileptiform patterns may be observed (14).

Cerebrovascular insufficiency in memory-related areas of the brain, due to a transient ischemic attack (TIA) or other hemodynamic compromise, could theoretically lead to transient memory loss. The vertebrobasilar and posterior cerebral arteries supply the temporal lobes, hippocampus, and thalamic nucleus (12). Case studies have reported that TGA may be an early warning sign of heparin-induced thrombocytopenia and antiphospholipid syndrome (15,16).

TGA may be confused with migraine, but a migraine typically presents with a prodrome and unilateral head pain associated with nausea (17). Hypoglycemia, hyperglycemia, uremia, and hypocalcemia may be associated with a change in mental status or a near-syncopal or seizure-like event that may be confused with TGA. Routine laboratory studies may help with the diagnosis. Illicit or prescription drugs may cause confusion or delirium. Specifically, there are cases describing an association between sildenafil (Viagra) and apparent TGA (18). Toxins such as solvents or heavy metals, as well as drug withdrawal, may cause similar symptoms.

Several cases have been reported of young healthy climbers at very high altitudes who experienced TGA. There were no injuries, neurologic abnormalities, or symptoms related to hypoxia. Upon partial descent from altitude, their symptoms resolved completely, and they were later able to tolerate higher altitudes (19). Head trauma may also lead to retrograde amnesia (difficulty recalling events from the immediate past) and anterograde amnesia (inability to learn new information after the injury) (17).

ED EVALUATION

The diagnosis of TGA is made by taking a thorough history. This involves speaking with a reliable witness to the preceding events. The physical examination, including a complete neurologic examination, is normal. Laboratory investigation should include electrolytes and a complete blood count. A computed tomography (CT) scan of the brain is usually obtained in patients with TGA, but it is of questionable utility. No clear relationship has been documented between any brain CT findings and TGA. Landi (20) documented a case of TGA due to a left temporal hemorrhage. Zorzon (21) reviewed 50 head CTs from patients diagnosed with TGA and observed one left occipital and one right temporal infarction. It was not clear from the study as to the “age” of the infarcts. Pai (12) noted that of 17 patients with TGA, two CT abnormalities were noted, an old left and right thalamic infarct.

Additional studies may include magnetic resonance imaging (MRI) with diffusion-weighted imaging (DWI) (22), single-photon emission CT (SPECT), PET imaging, and EEGs. MRI and SPECT studies performed during TGA episodes have shown temporal lobe changes (2,23,24). If MRI with DWI is performed too early in the course of disease, a negative study may be obtained (2). An MRI with DWI (25) has documented TGA with an acute infarction of the retrosplenium of the corpus callosum; the retrosplenial cortex is thought to allow for "memory" connections between the anterior thalamus and the medial temporal structures. Increased time lapse from symptom onset to MRI with DWI within the first 24 hours and increased field strength may increase detection rates (22). Recent studies involving PET imaging 2 hours after onset of symptoms of TGA revealed hypometabolism in the left hippocampus that correlated with findings of small nodular hyperintensities in the same region on MRI with DWI at 48 hours (26).

SPECT has demonstrated a decrease in blood flow to the thalamus (27) and ischemia in brain regions supplied by the posterior cerebral arteries that included the medial left temporal lobe and left thalamus (28). Pai (12) documented that the left temporal region was the most common site of dysfunction on EEG and SPECT. SPECT has shown a possible temporal relationship to areas of hypoperfusion. In the acute phase, significant hypoperfusion was seen in the right precentral, cingulate, and medial frontal gyri. At 1 month, significant hypoperfusion was seen in the right precentral and cingulate gyri, and the left postcentral gyrus, with resolution of changes at 1 year (29).

ED MANAGEMENT

TGA is a benign condition with a good prognosis. Although a vascular etiology has not been identified, daily aspirin therapy is suggested. When the diagnosis has been made, the patient and family require reassurance regarding the benign nature of TGA.

Patients with TGA do not appear to have a higher incidence of cardiovascular risk factors. TGA patients are at a very low risk of

subsequent stroke or myocardial infarction (MI). Additional TGA episodes occur in about 3.5% to 15% of patients at 3 to 7 years (3,7,8,11,30).

CRITICAL INTERVENTIONS

- Obtain an accurate and detailed history reported by a reliable observer.
- Perform a thorough neurologic examination.
- Rule out a CVA.
- Reassure the patient and the patient's family.

DISPOSITION

The typical patient with TGA has an uncomplicated course and a complete recovery. This is supported by imaging studies (29). If the diagnosis is clear and the episode has resolved, the patient may be discharged with family or friends. If symptoms persist or if there is any question about the diagnosis, the patient should be admitted to the hospital. A neurology consultation may be considered along with a further workup that may include an MRI and/or an EEG.

Common Pitfall

- Failure to consider the diagnosis.

CHAPTER 158

Peripheral Neuropathies

Phyllis A. Vallee and Christopher A. Lewandowski

The peripheral nervous system begins within the spinal canal with the ventral and dorsal nerve roots. These merge to form the spinal nerves, which then supply the visceral nerves, nerve plexuses, and peripheral nerves. Several generalizations can be made about the findings attributed to each of these areas. Lesions affecting the dorsal (afferent) roots produce pain, sensory loss, and decreased reflexes, but muscle strength is preserved. Ventral (efferent) root lesions produce muscle weakness, spasm, and autonomic symptoms without pain. A combination of all these symptoms occurs when spinal nerves are affected. Disorders affecting the visceral fibers will produce autonomic symptoms, which include extreme fluctuations in cardiac rhythm, blood pressure, gastrointestinal (GI) motility, urogenital function, sweating, and salivation.

Peripheral neuropathies are confusing entities; nevertheless, only 13% to 25% of patients undergoing intensive evaluation fail to have a diagnosis made (1,2). Emergency physicians evaluating patients complaining of symptoms consistent with peripheral neuropathy should determine the chronicity, pattern, and symmetry of symptoms to establish a working differential diagnosis (1,3,4). In general, peripheral neuropathies can be divided into several basic categories: polyneuropathy, plexopathy, radiculopathy, and mononeuropathy.

ACUTE POLYNEUROPATHY

Polyneuropathy results from the simultaneous dysfunction of multiple peripheral nerves. Symptoms include diffuse motor and/or sensory loss, with variable autonomic dysfunction. Polyneuropathies that develop over several days to 2 to 4 weeks are considered acute. Of these, Guillain–Barré syndrome (GBS) is the most common (4–6).

CLINICAL PRESENTATION

GBS, also known as acute inflammatory demyelinating polyradiculoneuropathy (AIDP), is a worldwide, nonseasonal, acute polyneuropathy that affects all ages, with a yearly incidence of 0.4 to 2.0 cases per 100,000 population (4,5,7,8). Pathologic examination reveals inflammation and segmental demyelination as the primary defect in about 90% of cases in North America and Europe (4,5,7,9). Primary axonal degeneration presenting as acute motor axonal neuropathy (AMAN) or acute motor and sensory axonal neuropathy (AMSAN) occurs in only 10% of cases in this region (7,9), but accounts for 30% to 65% of cases in China, Japan, Bangladesh, and Central and South America (5,9).

In classic GBS (AIDP), patients experience a prodromal event such as an upper respiratory tract infection, gastroenteritis surgery, vaccination, or infection with agents such as *Mycoplasma,* the herpes viruses, CMV, EBV, hepatitis B and C, and HIV. Overall, *Campylobacter jejuni* infection is the most commonly identified pathogen associated with GBS (4,5,8). In 1 to 3 weeks patients develop the onset of distal paresthesias and a symmetric ascending motor paralysis that progresses to its peak over 10 to 14 days. Motor weakness is both proximal and distal, with legs being involved prior to the arms and trunk. Additional findings include hyporeflexia or areflexia within 7 to 10 days of symptom onset, mild sensory losses, cranial nerve palsies (facial diplegia occurs in 50% of cases) (4), and autonomic dysfunction. Bowel and bladder disturbances are uncommon (15%) and brief in duration (4). Patients are afebrile and mental status is unaffected. It is not unusual for patients to initially present with low back, hip, and thigh pain that is confused with disc disease or lumbar strain.

The axonal variants of GBS (AMAN and AMSAN) tend to present in a more acute manner than AIDP and tend to have a worse prognosis (4). They also have a stronger association with preceding *C. jejuni* infection. The Miller-Fisher variant of GBS presents with ophthalmoplegia, ataxia, and areflexia. Other less common variants include pure sensory GBS, pure pandysautonomia, and pharyngeal–cervical–brachial GBS. These variants may make diagnosis difficult; however, when considering the differential diagnosis of classic GBS, marked or persistent asymmetry of weakness, lack of facial and respiratory muscle weakness in a patient with generalized paralysis, prolonged incontinence, a sharp sensory level, or fever strongly suggest an alternative diagnosis (7).

DIFFERENTIAL DIAGNOSIS

Tick Paralysis

Tick paralysis typically affects children in the spring and summer months. An acute ascending motor paralysis nearly identical to GBS results from a toxin present in the saliva of ticks (usually *Dermacentor* in the United States) that have been attached to a human host for a period of 5 to 7 days. Unlike GBS, sensory loss and CSF abnormalities are not seen in tick paralysis (10). The diagnosis is made when the offending tick is located, and treatment consists of its removal and supportive care. Symptoms begin to improve within hours of tick removal and generally resolve completely within 2 to 3 days. *Ixodes holocyclus,* a tick species found in Australia, is associated with paralysis that can progress despite tick removal. For this species, a hyperimmune serum has been developed (1,10).

Botulism

Exposure to botulinum toxin, which inhibits the release of acetylcholine at neuromuscular junctions, usually results from the ingestion of improperly canned foods, GI tract colonization in young infants fed raw honey, or rarely, from cutaneous infection with *Clostridium botulinum.* The toxin is a potential weapon of mass terror, and exposure may be via ingestion or inhalation. Initial

symptoms of botulism begin hours to several days after exposure and include nausea, vomiting, and dry mouth in patients who have ingested the toxin. Neurologic symptoms begin with cranial nerve palsies with prominent ocular findings (e.g., blurred vision, dilated pupils, diplopia). These are rapidly followed by symmetric, descending motor weakness and autonomic dysfunction. Sensation and mental status are not affected and fever is absent. Treatment consists of antitoxin therapy (available through the Centers for Disease Control [CDC]) and supportive care (1,10).

Poliomyelitis-Like Syndromes

In the United States, poliomyelitis is rare and nearly all cases are imported or related to the use of the live attenuated oral vaccine. Patients with polio first develop an acute viral illness with fever, headache, meningeal signs, muscle pain, and tenderness. These symptoms are present 1 to 2 days before weakness develops. Polio paralysis is more proximal than distal, legs are involved more than arms, and classically, involvement is asymmetric. Sensory loss is extremely rare, and its presence should raise the suspicion of other diagnoses. The most serious complication of polio is respiratory muscle paralysis. Progression of paralysis abates when patients become afebrile. A similar paralytic syndrome may occur following infection with other nonpolio enteroviruses or with the West Nile virus, a flavivirus introduced into the United States in 1999 (1,10,11).

Diphtheria

Diphtheria begins as a pharyngeal infection caused by an exotoxin-producing *Corynebacterium diphtheriae*. Subsequent toxicity, both cardiac and neurologic, correlates with the severity of the pharyngeal disease. Paralysis of local pharyngeal muscles, followed by cranial nerve palsies, occurs in the first or second week of infection. Cardiac toxicity begins 1 to 2 weeks after the onset of illness. The polyneuropathy, which is mainly motor, does not develop for 5 to 8 weeks. Weakness may begin in all extremities

simultaneously, or it may first appear in proximal muscles and then spread distally. Occasionally, the primary site of infection is a skin wound, in which case sensorimotor changes are first noted near the infected wound. Treatment of diphtheria involves use of antitoxin within the first 48 hours of acute infection. Treatment of the neuropathy consists of supportive care (4,10).

Acute Intermittent Porphyria

In this disorder, stimulation of an enzymatically deficient heme synthesis pathway results in the buildup of neurotoxic precursors. An acute attack classically begins with severe abdominal pain, which is followed by tachycardia, hypertension, and mental status changes. Seizures may occur. Within days, a sensorimotor polyneuropathy that can be symmetric or asymmetric, and ascending or descending, may develop and can progress to respiratory failure and death. Treatment consists of intravenous glucose and hematin to shut down the defective pathway, β-blockers to control hypertension, and supportive care (1,4).

Heavy Metals/Toxins

Most neuropathies due to heavy metal poisoning are subacute or chronic. Acute presentations are associated with thallium, massive arsenic, and organophosphate exposure. Thallium ingestion produces abdominal pain, vomiting, and diarrhea, followed by painful paresthesias and the rapid onset of diffuse motor weakness. Differentiation from GBS is often made 1 to 2 weeks after the onset of symptoms, when thallium-induced alopecia becomes apparent. Acute arsenic polyneuropathy, which is also clinically similar to GBS, begins 8 to 20 days after a large exposure and is associated with GI symptoms, renal failure, hepatic failure, and mental status changes. Organophosphates initially produce a cholinergic syndrome, but in 2 to 5 weeks a predominantly motor, distal symmetrical polyneuropathy may develop (4).

Others

Acute polyneuropathy may develop as a complication of critical illness, uremia and dialysis, malignancy, nutritional deficiencies, collagen vascular disease, infectious agents, or a host of toxins and drugs. These should be considered in patients with a presumptive diagnosis of GBS.

Neurologic and muscular disorders that produce weakness and must be differentiated from GBS include myelopathy, transverse myelitis, lumbar disc disease, myasthenia gravis, and acute myopathy. Within this category, cervical myelopathy deserves added attention. It presents with an ascending paraplegia or quadriplegia and a sensory level. Unlike GBS, it is associated with localized neck pain or tenderness, hyperreflexia (unless spinal shock is present), pathologic reflexes (e.g., Hoffman sign), and loss of sphincter tone. Respiratory compromise is not seen unless the cord is involved above the C5 level. Active or passive neck motion may exacerbate symptoms. Acute myelopathy is usually the result of trauma. Subacute myelopathy is seen with neoplasm, subdural, or epidural abscess, disc herniation, and hematoma; however, these etiologies may present with acute onset of symptoms, especially if the vascular supply to the cord is compromised. Patients who have symptoms suggestive of a myelopathy must undergo rapid imaging with a magnetic resonance imaging (MRI) or computed tomography (CT) myelogram as correct diagnosis, and intervention may prevent permanent deficits.

Metabolic disorders such as acute hypophosphatemia, hypokalemia, hypermagnesemia, hyperkalemia, and periodic paralysis may produce severe generalized weakness that may mimic GBS. Hysteria and malingering should also be considered in the differential diagnosis.

ED EVALUATION AND MANAGEMENT

Patients presenting with the acute onset of weakness warrant rapid assessment of airway, ventilatory capacity, and cardiovascular status. Following stabilization, history and physical examination, including a detailed neurologic examination, are the principal

methods of emergency department (ED) evaluation. The emergency physician should obtain a complete blood count, serum electrolytes, calcium, magnesium, phosphate, glucose, blood urea nitrogen, creatinine, chest radiograph, and electrocardiogram on all patients.

Additional studies might be obtained by the emergency physician if clinical evaluation raises the suspicion of a specific disease process. Otherwise, additional testing should be left to the consulting neurologist following characterization of the neuropathy by nerve conduction studies and electromyography (3).

Patients suspected of having GBS should undergo lumbar puncture. The characteristic findings are normal pressure and albuminocytologic dissociation (elevated protein levels with fewer than 10 mononuclear cells/μL). Cerebrospinal fluid changes may be delayed 1 to 2 weeks after the onset of symptoms. An increased cell count should raise the suspicion for HIV, West Nile virus, or Lyme disease as the precipitating event (1,4).

Baseline measurements of pulmonary function are important, because 25% to 33% of patients with GBS eventually require mechanical ventilation (1,4,5,9). Forced vital capacity (FVC) or negative inspiratory force (NIF) should be tested in the ED. A brief bedside test is to have the patient take a single deep inspiration and then quickly count for as long as possible; the ability to count to 20 correlates with an FVC of 1.5 L (4). FVC of $<$15 to 20 mL/kg or an IF of $<$20 to 30 cm H_2O are indications of imminent respiratory failure and the need to initiate mechanical ventilation (1,4,5,12). Patients who remain in the ED for several hours should have serial pulmonary function testing. Bulbar muscle strength should also be followed, as intubation may be required to maintain a patent airway and prevent aspiration. Frequent vital signs and continuous cardiac monitoring are essential to identify life-threatening cardiovascular autonomic dysfunction. Blood-pressure fluctuations should be treated, as needed, with fluids and short-acting agents.

DISPOSITION

Every patient with an acute polyneuropathy should be evaluated by a neurologist. Admission to the hospital for further diagnostic studies and continued monitoring of vital signs and respiratory status is required. Whether an intensive care unit (ICU) is necessary for all patients is controversial. Any patient with significant respiratory impairment, inability to protect the airway, or autonomic instability should be admitted to an ICU. Several clinical findings have been associated with a high rate of mechanical ventilation: FVC <20 mL/kg, NIF <30 cm H_2O, EF (expiratory force) <40 cm H_2O, more than a 30% reduction in FVC from baseline, <7 days from symptom onset to hospital admission, and the inability to cough, stand, or lift the elbows or head off the bed (12,13). The presence of any of these should prompt an ICU admission. For all other patients, the admission destination depends on the adequacy of monitoring in other settings. Patients with severe or rapidly progressive GBS benefit from early plasma exchange or immune globulin therapy (1,3,4,5,9); therefore, these patients should be transferred to a facility capable of providing such therapies.

Although the majority of patients with GBS recover completely or with minimal deficits, it should be noted that GBS has a 3% to 5% mortality (4,5). Ten percent to 20% of patients will have severe persistent deficits (3,4,5,9). In addition, 5% to 10% will have recurrent episodes of acute peripheral neuropathy (4,14).

Common Pitfalls

- Mistaking the low back pain of GBS for disc disease or back strain.
- Mistaking the symptoms of cervical myelopathy or other spinal cord pathology for GBS.
- Failing to admit patients with minimal, but suggestive, symptomatology.
- Inadequately monitoring for respiratory and autonomic dysfunctions.

- Ascribing the symmetric weakness of GBS or other acute polyneuropathies to a psychiatric disorder.
- Failing to recognize variant presentations of GBS.

SUBACUTE POLYNEUROPATHY

CLINICAL PRESENTATION

Polyneuropathy that develops over a period of several weeks to months is said to be subacute; however, the distinction between subacute polyneuropathy (SPN) and acute polyneuropathy is not always clear. SPN may be symmetric or asymmetric. Symmetric disease generally begins with distal sensorimotor losses and tends to produce marked sensory impairment. Asymmetric SPN is frequently the result of neuronal ischemia; nerves are randomly affected, producing patchy sensorimotor losses.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of SPN includes subacute or chronic inflammatory demyelinating polyneuropathy (CIDP), mononeuritis multiplex, and other neuromuscular diseases that produce subacute weakness such as myelopathy, myasthenia gravis, amyotrophic lateral sclerosis, Parkinson disease, and depression. However, perhaps more important to consider are the numerous toxic, nutritional, and systemic disorders that can result in SPN.

The etiologies for *symmetric* SPN include diabetes mellitus, alcoholism, nutritional deficiencies, uremia, amyloidosis, heavy-metal intoxication, industrial solvents (e.g., glue sniffing), paraneoplastic syndromes, and a multitude of toxins and medications. Collagen vascular disease, autoimmune diseases, and infections such as Lyme disease and HIV are much less common causes.

The etiologies of *asymmetric* SPN include diabetes mellitus (e.g., diabetic amyotrophy), collagen vascular and autoimmune diseases, peripheral vascular disease, sarcoidosis, neoplastic disease, paraproteinemia, leprosy, Lyme disease, and HIV infection.

ED Evaluation and Management

History and physical examination are the principal methods of evaluation. Key historic elements to elicit are a history of neuromuscular or systemic disease, medications (prescription and nonprescription), and potential infectious or toxic exposure. Laboratory studies should include complete blood count, serum electrolytes, calcium, magnesium, phosphate, glucose, blood urea nitrogen, creatinine, and a screening chest radiograph. As with acute neuropathies, further studies should be obtained only if a specific etiology is suspected following initial evaluation (3).

If a medication is suspected as the etiology, it should be discontinued or changed after consultation with the primary care physician. Short-term follow-up should be arranged.

DISPOSITION

Most patients with SPN may be referred to their primary care physician for outpatient evaluation and referral to a neurologist. A recent review found that optimal, evidence-based, outpatient diagnostic tests are often not done (15); therefore, it may be of value to discuss these with the patient's provider or mention them in discharge recommendations. These tests are as follows: glucose tolerance test, serum B_{12} with metabolites, and serum protein electrophoresis (2).

Common Pitfall

- Attributing SPN to a chronic medical condition, thus overlooking potentially treatable causes such as nutritional deficiencies, medication exposure, toxin exposure, infection, or vasculitis.

PLEXOPATHY AND RADICULOPATHY

CLINICAL PRESENTATION

A plexopathy is a disorder that affects the brachial or lumbosacral plexus. Symptoms include pain and mixed motor and sensory

deficits in a pattern that cannot be attributed to individual peripheral nerves or nerve roots.

Acute or subacute plexopathies are associated with local trauma (e.g., shoulder dislocation), compression (e.g., retroperitoneal hematoma or abdominal aortic aneurysm), vascular disease (usually due to diabetes or collagen vascular disease), infection (e.g., Lyme disease), or they may be idiopathic. Idiopathic lumbosacral plexopathy is uncommon (16), but acute idiopathic brachial plexopathy (Parsonage–Turner syndrome) though rare is well described (4,17). It is seen most commonly in young adults with a slight male predominance, and there appears to be some association with recent viral illnesses and immunizations (1,17). Symptoms of brachial plexopathy begin with the sudden onset of severe shoulder pain that may extend into the neck and upper arm. Less commonly, the lower plexus cords may be affected, producing symptoms in the forearm and hand. Within days to weeks, motor weakness and sensory loss develop, usually coinciding with resolution of pain (11,17). About 90% of patients recover good neurologic function by 3 years (17). There is recent evidence to suggest that this syndrome is heterogeneous, including both plexopathy and multiple mononeuropathies (17,18). Chronic plexopathy is associated with infections, vascular disease, collagen vascular disease, tumor, infiltrative processes, and radiation therapy.

In contrast to plexopathy, a radiculopathy affects spinal nerve roots or spinal nerves. Symptoms include pain and sensorimotor deficits in a pattern consistent with the involved nerve root (e.g., lancinating pain along the L-5 nerve root dermatome). Frequently, several adjacent roots are affected, making differentiation from a plexopathy or multiple mononeuropathies clinically impossible. The etiologies of radiculopathy include all those of a plexopathy, as well as specific spinal canal or cord disorders such as herniated disc, spinal stenosis, and epidural tumor, abscess, hematoma, granuloma, and infection (1,4).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of plexopathy includes polyneuropathy, multiple mononeuropathies, and spinal cord and nerve root disorders. Brachial plexopathy can easily be confused with cervical radiculopathy, and lumbosacral plexopathy with lumbosacral radiculopathy. The pain of idiopathic brachial plexopathy tends to resolve as motor symptoms develop, unlike the persistent pain of cervical radiculopathy. In addition, pain from cervical radiculopathy increases with neck movement, coughing, and sneezing, whereas brachial plexopathy pain does not. Pain from both lumbosacral plexopathy and lumbosacral radiculopathy is persistent; however, back pain is not a prominent feature of lumbosacral plexopathy (16).

Thoracic outlet syndrome can mimic brachial plexopathy by producing pain and weakness in the arm. Other local joint or tendon disorders, muscular disorders, and amyotrophic lateral sclerosis may also mimic plexopathy but can usually be differentiated by their lack of sensory abnormalities. Abdominal or retroperitoneal processes may cause irritation and pain in a distribution consistent with either a radiculopathy or plexopathy.

ED EVALUATION AND MANAGEMENT

The history and physical examination, including a detailed neurologic examination, are essential in management decisions. Motor findings are more reliable than sensory findings when evaluating the upper extremity (14). The pattern of muscle weakness is unique for each nerve root (C5–T1) and peripheral nerve. In the lower extremity, the sensory examination is more reliable than the motor examination when evaluating root disorders (14). The lower extremity sensory examination reveals root dermatomes that run horizontally or diagonally across the anterior leg, whereas the peripheral nerve dermatomes run vertically. A plexopathy will produce a pattern of muscle and sensory deficits that are a blend of both root and peripheral nerve pathology. Patten's *Neurological Differential Diagnosis* provides a detailed review of the complex clinical examination findings that will help

differentiate spinal nerve root versus plexus versus peripheral nerve disorders (14).

Patients with symptoms of *acute brachial plexopathy* should have cervical spine, chest, and shoulder radiographs. Laboratory studies such as complete blood cell count, serum electrolytes, glucose, blood urea nitrogen, creatinine, and sedimentation rate should be obtained if the history or physical examination suggests infection, diabetes, or collagen vascular disease.

Acute lumbosacral plexopathy generally occurs secondary to another disease process. A complete blood cell count, serum electrolytes, glucose, blood urea nitrogen, creatinine, erythrocyte sedimentation rate, and lumbosacral films are appropriate. An abdominal ultrasound or CT is indicated if an aortic aneurysm or other retroperitoneal pathology (e.g., bleed, tumor) is suspected. A determination of postvoid residual urine volume will aid in defining the extent of the neurologic deficit.

The approach to an *acute radiculopathy* is dictated by the history and physical examination. Whereas an evaluation consistent with an acute herniated disc and no objective neurologic deficits may require only conservative management with analgesia, muscle relaxants, limited activity, and close follow-up, the presence of objective deficits or another etiology will require an aggressive evaluation, including blood testing, a determination of postvoid residual urine volume, spinal imaging, and consultation.

In patients with chronic symptoms, minimal immediate diagnostic workup is necessary. A chest and neck radiograph or lumbosacral films are reasonable screening tools for such patients.

DISPOSITION

Acute symptoms resulting from plexopathies are often difficult to distinguish from root and spinal cord disorders (4); therefore, they generally require urgent neurosurgical consultation. Spinal CT, MRI, or myelography may be required to determine the correct diagnosis, and hospital admission to complete such testing is recommended.

Outpatient follow-up is appropriate for patients with chronic symptoms.

Common Pitfalls

- Attributing symptoms to mononeuropathy, and thereby failing to proceed with the appropriate diagnostic evaluation required for plexopathies and radiculopathies.
- Failing to consider potentially catastrophic etiologies for acute plexopathies (e.g., abdominal aneurysm).
- Failing to consider potentially catastrophic etiologies for acute radiculopathies (e.g., spinal epidural abscess or acute cord compression).

MONONEUROPATHY

CLINICAL PRESENTATION

Mononeuropathies produce variable symptoms of pain and sensorimotor loss in the distribution of a single peripheral nerve. Nerve compression (e.g., Saturday night palsy and meralgia paresthetica) and nerve entrapment (e.g., carpal tunnel syndrome) are the most frequently encountered etiologies for mononeuropathies seen in the ED. Entrapment syndromes have been associated with repetitive activity, pregnancy, rheumatoid arthritis, osteoarthritis, gout, hypothyroidism, acromegaly, amyloidosis, multiple myeloma, collagen vascular disease, and local tumors (5,15). Other causes of mononeuropathies are trauma, diabetes mellitus, peripheral vascular disease, collagen vascular disease, infection, granulomatous disease, infiltrative disorders, neoplasia, radiation therapy, and primary nerve tumors.

A unique form of mononeuropathy is mononeuritis multiplex. This entity involves the simultaneous or near-simultaneous dysfunction of two or more peripheral nerves. It may result from diabetes, multiple pressure palsies, infections (e.g., leprosy, Lyme disease, HIV infection), infiltrative or neoplastic disease, vascular disease, or collagen vascular disease (1). Overall, greater than 50%

of cases result from systemic vasculitis of the vasa nervorum (4). Abrupt onset of mononeuritis multiplex in patients with a collagen vascular disease or other vasculitis generally indicates an acute necrotizing vasculitis that requires aggressive treatment (14).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a mononeuropathy includes radiculopathy, plexopathy, polyneuropathy, local joint or muscular disorders, hysteria, and malingering.

ED EVALUATION AND MANAGEMENT

The evaluation of a mononeuropathy should focus on the nature of the deficit and historical factors such as duration, any traumatic injury, occupational factors (e.g., repetitive activity), or symptoms suggestive of diabetes, collagen vascular disease or vasculitis. The physical examination should determine whether the deficit fits the distribution of a single peripheral nerve. Provocative symptoms (e.g., Tinel sign and Phalen sign) may help elicit symptoms that are only episodic. Palpation along the course of the nerve may reveal areas of compression. Evidence of systemic disease should also be sought.

Complete blood cell count, electrolytes, blood glucose, erythrocyte sedimentation rate, antinuclear antibody testing, thyroid function tests, and serum protein electrophoresis are indicated only if a systemic disorder is suspected. Radiographs may be helpful in cases associated with trauma or when bone abnormalities are a possible cause of entrapment.

Identified etiologies, such as diabetes or repetitive activities, should be addressed. Patients with symptoms consistent with carpal tunnel syndrome may benefit from use of wrist cock-up splints.

DISPOSITION

Most patients with a mononeuropathy can be discharged with outpatient follow-up. Patients in whom the etiology is unclear should be referred to their primary care physician or a neurologist

for further testing, which may include nerve conduction studies and electromyography.

Urgent evaluation by a plastic surgeon, orthopedic surgeon, or neurosurgeon is indicated for posttraumatic mononeuropathy. Hospital admission is indicated for acute mononeuropathy multiplex in patients with known or suspected collagen vascular disease or vasculitis because this disorder usually indicates an acute necrotizing vasculitis, which requires aggressive steroid or other immunosuppressive therapy (15,19).

Common Pitfalls

- Failing to differentiate a mononeuropathy from a polyneuropathy, plexopathy, or radiculopathy.
- Failing to detect systemic signs of collagen vascular disease or other vasculitic disorder in patients with mononeuropathy multiplex.

KEY TESTING

Polyneuropathy:

- Acute onset: CBC, serum electrolyte, calcium, magnesium, phosphate, glucose, BUN, creatinine, lumbar puncture, CXR, EKG and pulmonary function testing
- Subacute onset: CBC, serum electrolyte, calcium, magnesium, phosphate, glucose, BUN, creatinine, lumbar puncture, CXR

Plexopathy:

- Acute Brachial Plexopathy: CXR, shoulder radiograph, cervical spine imaging
- Acute Lumbar Plexopathy: CBC, serum electrolyte, glucose, BUN, creatinine, ESR, lumbosacral spine imaging, postvoid residual urine volume

For All Peripheral Neuropathies:

- Testing done if clinical evaluation raises the suspicion of a specific disease process
- May include: MRI, CT scan, abdominal ultrasound, toxicology studies, thyroid studies, ESR, collagen vascular evaluation

CRITICAL INTERVENTIONS

- Perform rapid assessment of airway and ventilatory capacity, including measurements of pulmonary function, for patients with suspected GBS; repeat periodically and intubate when indicated.
- Perform lumbar puncture on patients suspected of having GBS.
- Recognize neurologic distribution (ascending vs. descending, proximal vs. distal, symmetric vs. asymmetric).
- Always consider and evaluate for the catastrophic causes of any acute radiculopathy or plexopathy.
- Admit patients with acute mononeuropathy multiplex and known or suspected collagen vascular disease or vasculitis.
- Elicit symptom onset, evolution of symptoms and prodromal illness or symptoms. Pay particular attention to medications and potential environmental, toxic or occupational exposures.

CHAPTER 159

Bell's Palsy and Trigeminal Neuralgia

Ross P. Berkeley

BELL&RSQUO;S PALSY

Bell's palsy is an acute, unilateral facial nerve (cranial nerve VII) neuropathy that causes peripheral weakness or paralysis of the muscles of facial expression. Named after Sir Charles Bell (1774 to 1842), the Scottish surgeon and anatomist who described the innervation of the facial muscles, this is the most common disorder affecting the facial nerve, with an annual incidence of approximately 15 to 30 per 100,000 persons. Bell's palsy is an idiopathic disorder equally affecting males and females, with a peak incidence in the second through fourth decades; there is no apparent predilection for one side of the face over the other (1–3). There is an increased prevalence during pregnancy, most commonly in the third trimester and the early postpartum period, compared with nonpregnant women of the same age. Case series have suggested that the onset of Bell's palsy during pregnancy may be associated with the development of preeclampsia (4,5). Additionally, there is an increased prevalence in patients with diabetes (6).

The pathophysiology of Bell's palsy is a subject of considerable debate, but edema of the facial nerve is suspected. Postulated etiologies include inflammation leading to compression of the facial nerve at the narrowest portion of its path through the temporal bone, the meatal foramen, possibly complicated by ischemic neuropathy and demyelination. Significant attention has been given

to herpes simplex virus type 1 as a possible etiologic agent, as it has been detected in the endoneurial fluid of the facial nerve of patients with Bell's palsy who have undergone surgical decompression, but its role in the pathogenesis of Bell's palsy has not been established (1,7,8). Genetics may play a role, as between 4% and 8% of patients with Bell's palsy have an associated family history (2,8).

CLINICAL PRESENTATION

Patients with Bell's palsy often report the rapid progression of facial weakness or paralysis, usually over hours or days, and frequently believe they may have had a stroke. There is typically drooping of the corner of the mouth, loss of the nasolabial fold, and difficulty closing the eye in patients with significant facial paresis. An observer may note upward movement of the eye on attempted closure of the affected eyelid (*Bell's phenomenon*). Although tear production tends to decrease, patients may experience tearing secondary to loss of lid control. Inability to completely close the eyelid, along with decreased lubrication, commonly causes eye irritation. Patients may note alteration or loss of taste (*ageusia*) in the anterior two-thirds of the tongue and may complain of abnormal sensitivity to sounds (*hyperacusis*) secondary to paresis of the stapedius muscle. Although some patients complain of subjective numbness on the affected side, sensation is preserved in Bell's palsy (3,9).

A facial palsy is readily evident on physical examination. It is critical, however, to distinguish a central from a peripheral facial nerve deficit. Since the muscles of the forehead are innervated by both cerebral hemispheres, a supranuclear (central) seventh cranial nerve palsy spares the function of the forehead. A patient with a unilateral central lesion, such as a cortical ischemic stroke, should therefore be able to wrinkle the forehead when asked to elevate the eyebrows, although the lower two-thirds of the face will be weak. With the peripheral facial nerve deficit seen in Bell's palsy, however, the entire face on the affected side will be weak, including the muscles of the forehead. As Bell's palsy is an isolated peripheral

neuropathy, any historical or physical examination evidence of central nervous system (CNS) involvement, or the presence of other neurologic and/or systemic findings, should prompt further evaluation and a thorough workup.

DIFFERENTIAL DIAGNOSIS

Bell's palsy is defined, in part, by its idiopathic nature and unilateral peripheral facial nerve involvement. It is a diagnosis of exclusion, and a comprehensive history, along with a diligent physical examination, is essential to exclude other potentially treatable or serious causes of facial nerve paralysis.

Lyme disease (see Chapter 185), caused by the tick-borne spirochete *Borrelia burgdorferi,* may cause a unilateral or bilateral facial nerve palsy. Evidence suggestive of Lyme disease may include a history of a tick bite, a rash consistent with erythema chronicum migrans (an expanding erythematous ring-like rash with partial central clearing), and arthralgias. Painless swelling and erythema of the face preceding the palsy may help distinguish a facial palsy caused by Lyme disease from a simple Bell's palsy (10). Serologic tests for the diagnosis of Lyme disease, such as immunoglobulin titers, may be misleading, and results are not generally available during an emergency department (ED) visit. In endemic areas, Lyme disease may be responsible for a significant proportion of cases of facial nerve paralysis (11), which may be mistakenly diagnosed as Bell's palsy; more than 50% of cases of pediatric facial paralysis are due to Lyme disease (8). As there may not be a known history of tick bite in many cases and because a large portion of patients fail to manifest an erythema chronicum migrans rash, the diagnosis of Bell's palsy should be called into question in such regions.

Ramsay Hunt syndrome (herpes zoster oticus) is the second most commonly identified cause of unilateral facial nerve palsy. It is classically accompanied by a painful vesicular rash in the external auditory canal, the anterior two-thirds of the tongue, or the soft palate. In some cases, however, vesicles may be absent or have a delayed appearance, termed *zoster sine herpete;* the presence of

dermatomal pain and dysesthesia should arouse suspicion of this entity (12). Involvement of the vestibulocochlear nerve (cranial nerve VIII) may result in hearing loss, tinnitus, or vertigo in up to 75% of cases (2). Ramsay Hunt syndrome is strongly suspected to be due to the reactivation of latent varicella virus in the geniculate ganglion in previously infected patients. Ramsay Hunt syndrome tends to present with more severe facial paralysis as compared with Bell's palsy, and the syndrome has a much lower rate of complete recovery (8). Early treatment with steroids and acyclovir within the first 72 hours is typically recommended.

Human immunodeficiency virus type 1 (HIV-1) is a neurotropic virus and may cause a facial palsy that is clinically indistinguishable from Bell's palsy during the period of acute seroconversion (13). In the later stages of HIV infection, a facial palsy is generally associated with advanced immunocompromise and is more commonly the result of opportunistic CNS infection or lymphoma. Mononeuritis multiplex can be associated with early HIV infection and may present with facial paralysis but, by definition, this vasculitic syndrome involves two or more distinct peripheral nerve regions. Milder cases of this syndrome may resolve spontaneously, although more severe cases may require use of intravenous immunoglobulin or steroids (14).

An acoustic neuroma, also known as a *vestibular schwannoma,* is a slow-growing benign tumor arising in the cerebellopontine angle. Patients typically present with progressive unilateral hearing loss over a prolonged period of time, as well as tinnitus, vertigo, and dysequilibrium. Unilateral facial weakness may occur as a result of facial nerve compression by the enlarging mass. A contrast-enhanced computed tomography (CT) with fine cuts through the skull base can be used as an initial screening test; however, magnetic resonance imaging (MRI) is the diagnostic modality of choice. Treatment may include surgical skull base excision or stereotactic radiosurgery to slow growth or treat postoperative residual tumor. Other causes of facial nerve compression include cholesteatoma, meningioma, and arteriovenous malformation (AVM).

Melkersson–Rosenthal syndrome is a rare disorder of unclear etiology, associated with recurrent episodes of facial palsy, orofacial edema leading to the development of lip scarring, and a fissured tongue. A partial palsy involving only one or two branches of the facial nerve should arouse suspicion of a parotid gland mass. Appropriate history and physical examination should readily identify facial nerve paresis caused by acute and chronic otitis media or mastoiditis. Other potential infectious etiologies include Epstein–Barr virus, cytomegalovirus, mumps, tuberculosis, and leprosy. A pontine lesion or infarction may cause facial weakness, as may multiple sclerosis, but there should be other commonly associated features to differentiate from Bell's palsy. Peripheral facial nerve palsies may also be caused by temporal bone trauma, amyloidosis, and Sjögren syndrome. Guillain–Barré syndrome and sarcoidosis may also cause a bilateral peripheral facial nerve palsy (1,3).

ED EVALUATION

A careful evaluation of the eye for corneal abrasions, including fluorescein staining with examination under a Wood's lamp, is warranted in patients with a complaint of visual disturbance or eye irritation, an inability to fully close the eyelid, or conjunctival injection. The external auditory canal and oropharynx should be inspected for vesicles, which are a defining feature of Ramsay Hunt syndrome. A thorough neurologic examination should be performed to confirm that facial weakness is not of central origin.

In the absence of other neurologic or systemic findings, a diligent history and physical examination demonstrating acute unilateral peripheral facial weakness permits a clinical impression of Bell's palsy, and further diagnostic evaluation (e.g., extensive laboratory work) is unnecessary. Diagnostic imaging is indicated only if there are atypical signs or symptoms, or if a patient recently diagnosed with Bell's palsy has no improvement after 3 or more weeks. In such cases, a CT of the head with fine cuts through the skull base is an appropriate screening examination. An MRI with and without

enhancement may be useful as a subsequent diagnostic modality, but this is rarely necessary during an ED evaluation.

KEY TESTING

- Careful ophthalmologic examination including evaluation for corneal abrasion
- Thorough neurologic examination

ED MANAGEMENT

ED management begins with reassurance to alleviate patient concerns regarding stroke or brain mass, along with a discussion of the overall prognosis and potential complications of Bell's palsy. Approximately 70% to 85% of patients with Bell's palsy can be expected to spontaneously recover normal facial function (Table 159.1), often within 3 months, although full recovery may take up to 9 months (2,15). The maximal extent of facial paresis is a key prognostic indicator: 94% of those with partial paresis experience spontaneous and complete recovery, whereas only 61% of patients with complete paralysis can expect a return of normal function. Younger patients have a significantly more favorable prognosis than those older than age 60. The disorder carries an approximately 7% to 8% recurrence rate of facial nerve paresis on either side (2,3).

TABLE 159.1
Poor Prognostic Indicators of Potential for Full Recovery

Complete facial paralysis
Age >60 yrs
Diabetes
Postauricular pain
Lack of signs of remission within first 2 wks of symptom onset

Patients should be educated regarding eye protection, including wearing glasses if there is incomplete closure of the lid, and advised to apply a lubricant eye ointment or tape the eyelid closed at bedtime to prevent corneal abrasions. Artificial tears should be

recommended to maintain eye lubrication during the daytime, especially when lacrimal gland function is compromised.

Although the majority of patients with Bell's palsy will spontaneously improve, the focus of pharmacologic treatment is to decrease the risk of development of long-term complications, some of which can be significant (Table 159.2). In a 2012 guideline update based on analysis of two Class I studies, the American Academy of Neurology recommends oral corticosteroids to increase the probability of complete facial nerve functional recovery, with a number needed to treat of 6 to 8. A course of oral prednisolone at 25 mg twice daily for 10 days, or at 60 mg daily for 5 days followed by a 5-day taper, can be considered (15–17). Steroids should ideally be started within the first 3 days of symptom onset; despite a lack of compelling evidence, such treatment may be considered for patients presenting as far out as 7 days (18). Although there is a paucity of evidence supporting a definitive therapeutic effect, antiviral agents may potentially confer an incremental benefit in recovery from Bell's palsy, and can be considered as an adjuvant therapy to steroids (16).

TABLE 159.2
Potential Long-Term Sequelae of Bell's Palsy

Partial or complete unilateral facial weakness and asymmetry
Recurrent corneal abrasions, corneal ulceration, and exposure keratitis
Hemifacial spasm
Hyperacusis: due to paresis of the stapedius muscle
Dysgeusia: impairment of taste; or *ageusia:* loss of taste
Motor synkinesis: involuntary facial movements accompanying purposeful movement of other muscle groups; due to aberrant facial nerve regeneration
Crocodile tear syndrome (gusto-lacrimation): spontaneous unilateral tearing in response to salivation, due to autonomic synkinesis; rare

CRITICAL INTERVENTIONS

- Differentiate between central and peripheral cranial nerve VII palsy.

- Rule out other causes of facial nerve deficit.
- Perform a thorough ophthalmologic examination.
- Educate the patient regarding eye protection.

DISPOSITION

Patients with Bell's palsy should be discharged with close ear, nose, and throat follow-up. Ophthalmology follow-up should be arranged for patients with extensive corneal abrasions or complete facial paralysis. Surgical decompression of the facial nerve in the management of Bell's palsy is somewhat controversial and is not supported by the American Academy of Neurology in its evidence-based review of the literature (18). However, proponents of early surgical intervention recommend that patients with complete facial paralysis who do not respond to medical therapy within 2 weeks of onset should be promptly referred for electroneurography and possible surgical decompression.

The facial distortion and potential social stigma caused by Bell's palsy may be a source of embarrassment for patients, and the impairment of facial expression may affect social interactions. Referral to a facial plastic surgeon may be considered for those with long-standing paralysis. Due to the ocular complications associated with the inability to completely close the eyelid and decreased tear production, patients may benefit from implantation of a gold weight in the upper lid. Facial spasm and synkinesis may be managed by botulinum toxin injections.

Common Pitfalls

- Expensive and unnecessary diagnostic workup for a simple case of Bell's palsy
- Missed corneal abrasion
- Missed comorbidities (e.g., diabetes) that may have predisposed the patient to the disease process
- Prematurely diagnosing Bell's palsy without considering other potential causes of facial paresis

TRIGEMINAL NEURALGIA

Trigeminal neuralgia (*tic douloureux*) is a neuropathic disorder of the trigeminal nerve characterized by recurrent episodes of unilateral facial pain. The trigeminal nerve (cranial nerve V) contains sensory fibers that innervate the face, the mucous membranes of the oral and nasal cavity, and the cornea; its motor fibers innervate the muscles of mastication. Trigeminal neuralgia has an annual incidence of approximately 4.5 per 100,000 persons and typically occurs in those older than 50 years of age, with a female-to-male ratio of 3:2 (19). The right side of the face is slightly more commonly involved. In the rare instances of bilateral involvement, paroxysms of pain never occur simultaneously on both sides of the face (20).

The pathophysiology of trigeminal neuralgia is not completely understood, but it is currently believed to be caused in most cases by an overlying blood vessel compressing the trigeminal nerve near the zone where the root enters into the pons. Episodic pain may result from the spontaneous generation of repetitive action potentials along with cross-excitation of neighboring axons (20–22).

CLINICAL PRESENTATION

The paroxysms of unilateral facial pain in trigeminal neuralgia are acutely intense, lasting from a few seconds to <2 minutes, and patients may experience hundreds of episodes each day. The pain is classically described as excruciating, with a lancinating, stabbing, or electric shock–like quality, and often causes unilateral spasmodic facial contraction or grimacing. The syndrome most commonly affects the maxillary branch (second division; V2), followed by the mandibular branch (third division; V3). Involvement of the ophthalmic branch (first division; V1) is uncommon. Symptoms may be present in the distribution of two contiguous divisions of the trigeminal nerve. Patients often experience *allodynia,* a painful response to non-noxious stimuli. In many cases, episodes may be evoked by trivial stimuli within the trigeminal distribution. Paroxysms may be initiated in such “trigger zones” by lightly

touching a particular region on the face, applying makeup, washing or shaving, chewing, or even by a light breeze.

Trigeminal neuralgia initially presents as a relapsing–remitting disease, with asymptomatic intervals lasting months or years. Over time, however, exacerbations occur with progressively increasing frequency. As pain becomes more sustained, symptoms can become incapacitating. Some patients become fearful of chewing or shaving and may develop an aversion to touching the face.

DIFFERENTIAL DIAGNOSIS

The evaluation of craniofacial pain requires a detailed history and physical examination, and the diagnosis of trigeminal neuralgia should be one of exclusion. Secondary causes of the clinical syndrome of trigeminal neuralgia, including a cerebellopontine angle tumor, aneurysm, or AVM, should be ruled out. In 2% to 4% of cases, trigeminal neuralgia may also be caused by demyelinating diseases such as multiple sclerosis, a diagnosis that should be considered particularly in younger patients (22).

Herpes zoster (shingles), caused by reactivation of dormant varicella zoster virus in sensory ganglia, commonly affects the ophthalmic branch (V1). Patients often present after the typical painful vesicular rash has appeared in a dermatomal distribution, making the diagnosis straightforward. In the prodromal phase prior to onset of the rash, however, patients may complain of a severe unilateral burning or pruritic pain, which is constant; this is distinct from the episodic pain of trigeminal neuralgia. Aggressive treatment within 72 hours of symptom onset with antivirals, such as acyclovir, is generally recommended, but the role of steroids remains controversial. Involvement of the cornea in herpes zoster ophthalmicus requires ophthalmologic consultation.

Postherpetic neuralgia involving the facial nerve, which can occur in 10% of cases of herpes zoster, may cause persistent unilateral facial pain lasting months after the vesicular rash has resolved. The incidence rises with increasing age. This neuropathic pain is typically described as burning and continuous. A history of recent

herpes zoster in the affected dermatomal distribution is key to diagnosis. In addition to opioids, pharmacologic agents commonly utilized for pain management may include tricyclic antidepressants, such as amitriptyline or gabapentin (Neurontin).

Glossopharyngeal neuralgia presents with episodic unilateral pain similar to trigeminal neuralgia, but it is much less common. This syndrome is suspected to result from vascular compression of the glossopharyngeal nerve (cranial nerve IX) (21). Sensory stimulation of trigger zones in the oropharynx typically provokes paroxysms of pain in the ear, throat, or neck, and symptoms may be triggered by swallowing, yawning, or coughing. Nervus intermedius or geniculate neuralgia is extremely uncommon and may cause severe paroxysms of lancinating or stabbing pain deep within the ear.

Temporal arteritis (giant-cell arteritis) characteristically presents with unilateral pain in the temple or forehead and may include symptoms of jaw claudication or episodic unilateral visual loss (*amaurosis fugax*). The pain is typically continuous without the shooting paroxysms seen in trigeminal neuralgia, and there is tenderness upon palpation of the temporal artery.

Other causes of facial or orbital pain such as sinus infection, orbital cellulitis, and glaucoma should be considered. Temporomandibular joint dysfunction may cause facial or otic pain accompanied by a history of jaw popping or clicking, in addition to localized tenderness or limited range of motion of the mandible. Odontogenic pathology including dental caries, dental fractures, or pulpitis should be apparent on physical examination. Oral galvanism, an unusual etiology of facial pain often accompanied by a metallic taste, may be caused by an intraoral electrical current between dissimilar metals in the dental amalgam or crowns of neighboring teeth (23).

ED EVALUATION

The diagnosis of trigeminal neuralgia is made primarily on a clinical basis and requires a thorough history and physical examination. Focused attention should be dedicated to examination of the head

and neck, especially the oropharynx and teeth. Observers may note wincing or facial grimacing in association with paroxysms, which may also be provoked by lightly touching the trigger zones. The neurologic examination should be normal, with no objective abnormalities of the motor or sensory function of the trigeminal nerve. Any sensory deficit should prompt consideration of possible trigeminal nerve compression secondary to a CNS space-occupying lesion, or of multiple sclerosis, and warrants cerebral imaging. Patients with dysfunction of other cranial nerves, signs of increased intracranial pressure, or bilateral or intractable symptoms should initially undergo emergent CT of the head with fine cuts through the skull base. Subsequent diagnostic imaging with MRI and MRA is generally recommended.

KEY TESTING

- Thorough neurologic examination
- CT or MRI of brain if abnormal neurologic examination

ED MANAGEMENT

Patients should be educated regarding the prognosis of the disease, and realistic expectations should be set. In the ED, the severe pain accompanying trigeminal neuralgia may require opioid analgesics. Carbamazepine (Tegretol) is the first-line agent recommended for long-term pharmacologic management and results in good pain control in 70% of patients (20,24). It is commonly initiated at 200 mg daily, and increased by 200 mg/day until symptoms are controlled, up to a maximum dose of 1,200 mg daily. Other anticonvulsants may be required to control symptoms, sometimes in combination, including oxcarbazepine (Trileptal), lamotrigine (Lamictal), phenytoin, valproic acid, and clonazepam, in addition to gabapentin (Neurontin) and baclofen (24). Over time, the response to medications tends to decrease. Some patients, particularly those of older age, may not tolerate the CNS side effects of carbamazepine, which may include drowsiness, dysequilibrium, or confusion. Patients with intractable symptoms may develop

depression and should be directly questioned regarding suicidal ideation.

CRITICAL INTERVENTIONS

- Rule out CNS masses and vascular lesions as the cause of symptoms.
- Rule out odontogenic and other local causes of facial pain.
- Provide adequate pain relief.

DISPOSITION

Once the diagnosis of trigeminal neuralgia has been carefully made on clinical grounds and CNS disease has been ruled out, patients may be discharged home as long as their pain has been adequately controlled. Close follow-up should be arranged to monitor serum carbamazepine levels and response to therapy. Patients may require referral to a neurologist or pain management specialist. Nonemergent surgical intervention may be indicated for those with persistent symptoms that fail to respond to medical therapy. Several options exist, but no procedure is universally effective. Microvascular decompression via suboccipital craniotomy demonstrates a high level of success for immediate and long-term relief from symptoms (25). Less invasive options, performed via percutaneous intervention, include radiofrequency thermal ablation of the trigeminal nerve or Gasserian ganglion, balloon microcompression, and glycerol rhizotomy (24). All of these procedures may result in dysesthesias (22). Stereotactic radiosurgery via gamma knife is a promising alternative, although long-term outcome data are lacking.

Common Pitfall

- Although a patient may have a history and physical examination that suggest a diagnosis of trigeminal neuralgia, this should be a diagnosis of exclusion, given the potentially serious alternatives to be considered.

CHAPTER 160

Myopathies and Disorders of Neuromuscular Transmission

Erik Nordquist

Although weakness is a common complaint of patients presenting to the emergency department (ED), it is not commonly caused by a primary muscle disorder or a disorder of neuromuscular transmission. Diagnosis and management of these disorders present particular challenges to the emergency physician because these disorders are rare and their clinical presentation is often subtle and variable.

Many neuromuscular disorders can present with rapidly progressive generalized weakness that can potentially cause life-threatening ventilatory compromise. It is important for the emergency physician to have an organized approach that is safe, quick, and thorough.

Commonly recognized conditions fall into the categories of myopathies (diseases of the muscle), disorders of the neuromuscular junction (myasthenia gravis [MG]), or peripheral neuropathies.

MYOPATHY

Myopathy is a muscle disease unrelated to any disorder of innervation or neuromuscular junction. Primary muscle disease presents with muscle weakness as the predominant symptom.

Impaired function while performing activities of daily life and muscle pain may be some of the other symptoms.

CLINICAL PRESENTATION

Weakness is generally progressive, proximal, and symmetric in distribution. Myopathy typically spares the extraocular, facial, and bulbar muscles (distinguishing the myopathies from MG and other disorders of neuromuscular junction). Although myopathic disease has gradual onset with a slow progression of symptoms, rapidly progressive generalized weakness can occur. An overview of the spectrum of myopathic disorders is given in Table 160.1.

TABLE 160.1
Classification of Myopathies

Inflammatory
Collagen vascular diseases (polymyositis, dermatomyositis, SLE, RA)
Idiopathic
Other (granulomatous, eosinophilic)

Infectious
Trichinosis

Hereditary myopathies include the various forms of muscular dystrophy, the metabolic myopathies, and periodic paralysis. Muscular dystrophies are chronic, progressive, inherited myopathies that present from early childhood to adolescence. The various types are differentiated by mode of inheritance, age at onset, rate of progression, and selectivity of muscle involvement (1). Duchenne dystrophy, observed in boys younger than 5 years, causes the most severe disease. Cardiomyopathy is common in affected children. Weakness and muscle wasting in a child with marked elevation of creatine kinase (CK) (10 to 20 times normal) occurs with Duchenne dystrophy, but other dystrophies (e.g., fascioscapulohumeral, limb-girdle, myotonic) are associated with more modest CK levels. Patients with mild cases may lead fairly normal lives, but progressive weakness and scoliosis impairing pulmonary function often result in recurrent infections and exacerbation of weakness. Diagnosis of muscular dystrophies is made on the basis of family history, clinical features, and the results of CK determination, electromyography, and muscle biopsy.

Metabolic myopathies are disorders of glucose or lipid utilization and energy production in skeletal muscle. They have common abnormalities of muscle energy metabolism that result in skeletal muscle dysfunction. Metabolic myopathies have a wide age range of symptom onset. Most patients present early in life (i.e., infancy, childhood, young adulthood).

Metabolic myopathies present with exercise intolerance, muscle cramps, and myoglobinuria. Cramps and muscle discomfort may occur after brief exercise or after prolonged physical activity. Glycogen is the main source of energy during brief exercise, and free fatty acids are the most important source of fuel during prolonged exercise. Cramps are the hallmark of glycogen-storage diseases (e.g., McArdle disease). In lipid-storage disease (e.g., carnitine palmity transferase [CPT] deficiency), muscle discomfort and exercise intolerance occur only after prolonged exercise and are worse during fasting (2).

Metabolic myopathies presenting with progressive muscle weakness may mimic limb-girdle muscular dystrophy or

polymyositis and are a common manifestation of deficiencies of acid maltase, debrancher enzyme, and carnitine.

Periodic paralyses are a group of diseases that cause patients to present with acute weakness caused by potassium shifts, leading to muscle dysfunction. A genetic defect of the potassium, calcium, or sodium-ion channels in muscle cell membranes is responsible for the paralysis, which may last from hours to days. Acute periodic paralysis may be classified as hypokalemic or hyperkalemic.

Acute hypokalemic periodic paralysis may be primary (i.e., familial) or secondary to excessive renal or gastrointestinal (GI) losses. In these cases, intracellular shift of potassium depolarizes the cell membrane, rendering it inexcitable. No muscle contraction can occur; hence, the patient experiences paralysis. However, paralysis of the respiratory muscles is uncommon.

The diagnosis of hypokalemic periodic paralysis is based on patient history, serum potassium determination (usually 2.5 to 3.5 mEq/L during attacks), and occasionally provocative testing performed in a controlled setting by a neurologist. In Asians and Hispanics, hypokalemic periodic paralysis can occur in association with thyrotoxicosis, so thyroid function tests should also be ordered (3). Familial periodic paralysis usually occurs in Caucasian males, is autosomal dominant, and may last as long as 36 hours. Attacks generally occur at night or in early morning upon awakening and can be precipitated by a diet high in carbohydrates, rest following exercise, or stress (4).

In the hyperkalemic form of periodic paralysis, attacks are more frequent, are of shorter duration (usually <2 hours), and are provoked by cold exposure, rest following exercise, fasting, or the ingesting of potassium (4). During an attack, the serum potassium is in the range of 5 to 7 mEq/L.

Polymyositis, an inflammatory disorder of skeletal muscle, is the most common primary myopathy to affect adults. Muscle damage is caused by T-cell–mediated and compliment-mediated autoimmune attack. Clinically similar to adult polymyositis, dermatomyositis is an idiopathic inflammatory myopathy associated with characteristic

dermatologic manifestations. Dermatomyositis is frequently associated with an underlying malignancy.

Symptoms of adult polymyositis gradually develop over a period of 3 to 6 months. Diagnosis is usually delayed because, unlike in dermatomyositis, no associated rash occurs before onset of muscle disease. Patients usually present with symmetric proximal muscle weakness in the upper and lower extremities. Distal muscle weakness may occur late in the course of the disease. Patients may report muscle pain and tenderness that may be confused with polymyalgia rheumatica. Constitutional symptoms include morning stiffness, fatigue, anorexia, fever, and weight loss. Dysphagia secondary to oropharyngeal and esophageal involvement occurs in about a third of patients and is a poor prognostic sign. Dysphonia is also a poor prognostic sign but is much less common. Ocular muscles are never involved in generalized polymyositis. However, isolated orbital myositis, an inflammatory disorder involving the extraocular muscles, is well described. Facial and bulbar muscle weaknesses are extremely rare manifestations.

The diagnosis of polymyositis is made on the basis of a combination of proximal muscle weakness, elevated muscle enzymes, detection of autoantibodies, characteristic electromyogram, and muscle biopsy (5). The erythrocyte sedimentation rate is often normal or only mildly elevated and is not a reliable indicator of disease severity.

DIFFERENTIAL DIAGNOSIS

Myopathic weakness may be caused by MG, inflammatory polyneuropathy (Guillain–Barré syndrome), neurotoxin exposure (e.g., botulism, tick paralysis, organophosphate poisoning), severe electrolyte abnormalities, drug- and alcohol-induced myopathy, periodic paralysis, and rarely polymyositis.

The differential diagnosis of subacute or chronically progressive weakness includes polymyositis, the muscular dystrophies, MG, polymyalgia rheumatica, and drug-induced myopathy. Proximal muscle weakness can also present because of hypothyroidism,

hyperthyroidism, hyperparathyroidism, Addison disease, Cushing syndrome, hypokalemia, hypophosphatemia, or hypomagnesemia. Chronic alcohol abuse can produce a syndrome of proximal muscle weakness and wasting, often with coexistent evidence of alcoholic peripheral neuropathy.

ED EVALUATION

In the face of profound weakness, immediate attention to the ventilatory status and airway stabilization are indicated before performing a detailed history and physical examination. Patient evaluation should focus on distinguishing neurologic from muscular dysfunction. Key components of the history include onset and time course, symmetry and fluctuation of symptoms, sensory deficits, involvement of proximal or distal muscle groups, association with activity such as climbing stairs, difficulty swallowing, precipitating factors, associated pain or stiffness, and sensory deficits. Complaints that suggest a central nervous system origin include diplopia, dysphagia, ataxia, or hemiparesis. Proximal muscle involvement causes difficulty performing activities such as rising from chairs, getting out of the bathtub, climbing stairs, and combing hair. Distal muscle involvement is suggested by weak grasp and handwriting problems.

Information should also be elicited about family history, underlying medical illnesses, medication use, and exposure to homemade or contaminated food. Steroids (especially fluorinated steroids), lipid-lowering agents, azidothymidine, alcohol, colchicine, pentachlorophenol (PCP), heroin, and cocaine may cause myopathies.

On physical examination, the patient should be tested for the ability to perform simple tasks (e.g., lifting arms above head, ability to make a tight fist, rising on the toes, or rising from the chair). Determine the distribution of muscle involvement including the extraocular, facial, or bulbar musculature. Pathologic muscle fatigue may be elicited by having the patient sustain an upward gaze, count loudly, or hold the arms horizontally. The muscles should be

inspected for size and irritability and palpated for tenderness. The neurologic examination must include an evaluation of pupillary size and reactivity, sensory function, and deep tendon reflexes (DTRs). DTRs and sensory perception should be normal in myopathies. DTRs may be diminished or absent in hypokalemic paralysis. A careful search for an adherent tick is important when appropriate.

Using the history and physical examination, it is generally possible to exclude disorders of neuromuscular transmission such as MG, peripheral neuropathy, and lower and upper motor neuron disease from the diagnosis of myopathy. The diagnosis of MG is suspected on the basis of weakness and fatigability in the typical distribution without loss of reflexes or impairment of sensation or other neurologic function. Peripheral neuropathy is characterized by areflexia, sensory ataxia, varying degree of cutaneous sensory deficit, and variable degrees of motor dysfunction. Lower motor neuron dysfunction and early denervation is characterized by insidiously developing asymmetric weakness, progressive muscle wasting and atrophy, and loss of DTRs. Finally, upper motor neuron disease is characterized by spasticity in the extremities (usually legs more than arms), brisk tendon reflexes, up-going plantar reflexes, and minimal to no sensory deficits.

Essential laboratory studies should include a complete blood count, erythrocyte sedimentation rate, thyroid function test, CK with isoenzymes, electrolytes, calcium, magnesium, phosphorus, myoglobin, serum creatinine and blood urea nitrogen (BUN), urinalysis (looking for myoglobin), chest x-ray (CXR), and ECG. Arterial blood gas (ABG) and bedside spirometry or peak flow should be performed to evaluate for ventilatory compromise.

KEY TESTING

- CBC
- Electrolytes, calcium, magnesium, phosphorus, myoglobin, serum creatinine, and BUN
- Erythrocyte sedimentation rate
- Thyroid function test

- CK with isoenzymes
- Urinalysis for myoglobin
- ABG and bedside spirometry/peak flow to evaluate for ventilatory compromise

ED MANAGEMENT

In patients with neuromuscular disease presenting with severe and rapidly progressing weakness, the crisis is usually precipitated by an intercurrent illness, most commonly a respiratory tract infection. These patients often present with ventilatory compromise, ineffective cough, and difficulty handling secretions. Decompensation to respiratory failure can be rapid. Immediate attention should be directed to oxygenation and ventilatory status. Serial physical examination, ABG determination, and spirometry are essential, and endotracheal intubation should be performed at the earliest sign of difficulty. Normal levels of pCO_2 and pO_2 are often maintained nearly to the point of profound respiratory failure and respiratory arrest.

The need for intubation and mechanical ventilation is best guided by serial measurement of vital capacity. A declining vital capacity or a vital capacity <15 mL/kg is an indication for urgent intubation. Patients with severe weakness should be ventilated, at least initially, in the controlled mode.

Attention to hemodynamic stability is the next priority, with continuous electrocardiographic monitoring and evaluation of fluid needs. CK determination and urinalysis are mandatory to identify acute rhabdomyolysis.

For polymyositis, prednisone is the first-line treatment of choice. Typically, the dose is 1 mg/kg/d, either as a single dose or divided. This high dose is usually continued for 4 to 6 weeks, until the muscle strength improves. Corticosteroid myopathy can occur during the course of treatment and must be distinguished from reactivation of muscle disease. CK level is usually within reference ranges in cases of steroid myopathy. No improvement is observed with higher doses of steroids, and the condition worsens if the dose

is increased. Immunosuppressive agents, such as methotrexate, azathioprine, or mycophenolate mofetil, are often initiated with the steroid therapy or may be reserved for patients who do not respond to initial therapy. Patients with poor prognostic indicators, such as dysphagia or dysphonia, usually require immunosuppressive agents.

Acute attacks of the hyperkalemic form of periodic paralysis often do not require treatment as they are brief. However, in more severe attacks, calcium gluconate (1 to 2 g IV) or glucose and insulin (1 amp $D_{50}W$ with 5 units of regular insulin IV) can be given. To prevent attacks, chronic therapy with a thiazide diuretic or acetazolamide may be given.

Treatment of acute hypokalemic periodic paralysis includes 60 to 120 mEq KCl given incrementally. Potassium administration should proceed slowly, as total body potassium stores are generally normal, to avoid posttreatment hyperkalemia. Acetazolamide prophylaxis and avoidance of high-carbohydrate meals are useful in chronic management (4).

DISORDERS OF NEUROMUSCULAR TRANSMISSION

The neuromuscular junction is the critical link between the central nervous system and the musculoskeletal system. Maintaining integrity of neuromuscular transmission is essential for effective communication between nerve and muscle and is required for maintaining skeletal muscle function, including the mechanism of breathing. Although disease states associated with malfunction of the neuromuscular junction only rarely present in the ED, these conditions are potentially fatal ailments; therefore, they must be considered in all patients who present with isolated or generalized muscle weakness of unknown etiology (Table 160.2). Alternatively, these disorders can be divided according to the site of derangement as seen in Table 160.3.

TABLE 160.2
Disorders of Neuromuscular Transmission

Myasthenia gravis
Congenital myasthenia
Snake venom

The hallmark of weakness associated with failure in neuromuscular transmission is fatigability. The patient may present to the ED with complaints of gradual weakness followed by the precipitous onset of muscular exhaustion. Typically, muscle weakness resolves briefly after a short rest and then worsens again. Neuromuscular transmission failure should also be considered in patients who report complaints of more generalized symptoms such

as chronic fatigue and shortness of breath, especially when there is no other obvious explanation for the clinical presentation.

MYASTHENIA GRAVIS

Clinical Presentation

MG, the most common disease of neuromuscular transmission, is an autoimmune disorder in which antibodies are directed against the acetylcholine (ACH) receptor, reducing the number of available receptors and impairing neuromuscular transmission (6). This disease is almost always associated with an abnormality of the thymus gland, either thymoma (15%) or thymic hyperplasia (75%). The thymus appears to be the site where B cells are sensitized to the ACH receptors, initiating the disease process. A reduction in the number of ACH receptors results in a characteristic pattern of progressively reduced muscle strength with repeated use of the muscle and recovery of muscle strength following a period of rest.

The incidence of MG is estimated to be about 15 per million people (6). The disease is most common in women in their mid-twenties, although it can occur at all ages. The peak incidence for men is the sixth to eighth decade of life.

The hallmark of MG is pathologic fatigue, caused by the loss of the generous physiologic reserve that normally supports transmission across the neuromuscular junction. Muscle weakness worsens with sustained activity and improves with rest. Patients commonly report worsening of symptoms as the day progresses.

MG is a disease of insidious onset, developing over a period of weeks to months. The muscle weakness occurs at first in transient attacks, at times precipitated by infection, stress, or pregnancy. The extraocular muscles are most commonly affected, and the most typical presentation is one of recurring episodes of diplopia and ptosis that are often noticed later in the day. There may be weakness of eye closure, weakness of the muscles of facial expression, or difficulty chewing. Transient dysarthria and dysphagia are common. Patients may also have involvement of the

proximal limb, truncal, and respiratory muscles and note difficulty climbing stairs or combing their hair.

The disease is extremely variable in its clinical presentation and may affect diverse muscle groups in an asymmetric, unpredictable manner, fluctuating in intensity over time. Spontaneous remissions and relapses are common, and the ultimate progression of the disease is highly variable. Respiratory crisis requiring mechanical ventilation occurs in up to 20% of patients.

Differential Diagnosis

The differential diagnosis includes drug-induced myasthenia, Lambert–Eaton myasthenic syndrome, neuroasthenia or psychoneurotic fatigue, botulism, inflammatory polyneuropathy (Guillain–Barré syndrome), periodic paralysis, and other causes of oculomotor paralysis (diabetes, multiple sclerosis, aneurysm). History, physical examination, and simple laboratory investigations should enable the emergency physician to readily distinguish between these entities. It is important for the emergency physician to consider the possibility of one of these diagnoses before making a diagnosis of functional or psychiatric illness.

ED Evaluation

The clinical evaluation of the patient presenting with a history of episodic weakness and fatigue involving extraocular, facial, or bulbar musculature should focus on obtaining a careful history, ruling out an underlying precipitating illness, demonstrating pathologic fatigue on physical examination, and considering possible etiologies.

On physical examination, the physician can perform provocative maneuvers, the simplest being extraocular movements. Fatigue with repeated muscle contraction supports the diagnosis. Other maneuvers that may be used to unmask underlying neuromuscular fatigability include having the patient count up to 100 or chew for 30 seconds while observing signs of functional deterioration. It is important to remember that the patient with MG has normal pupils,

DTRs, and sensation. A major focus of evaluation of MG in the ED is ongoing evaluation of the patients' respiratory status and ability to handle secretions. Bedside spirometry is helpful as a baseline as is ABG analysis looking for evidence of CO_2 retention.

The clinical diagnosis of MG is supported by noting a positive response to a bedside test (Tensilon test or ice pack test). IV edrophonium chloride (Tensilon) is a short-acting anticholinesterase inhibitor. Administration produces rapid improvement of ocular symptoms in patients with MG. Edrophonium should be used with caution, especially in cardiac patients, because of its potential for causing bradycardia. When this test is performed, the patient should be placed on a monitor, and atropine should be available at the bedside. Administer 2 mg of edrophonium IV. This dose can be repeated every 60 seconds up to a total dose of 10 mg. Evaluate the patient for improvement of weakness after each dose. Reversal of eyelid ptosis is the most specific sign. A false-positive response to edrophonium chloride has been reported in amyotrophic lateral sclerosis, Lambert–Eaton myasthenic syndrome, Guillain–Barré syndrome, wound botulism, cavernous sinus lesions, poliomyelitis, and alcoholic myositis (7).

The ice pack test will often improve ptosis in patients with MG. In the ice pack test, a bag of ice is applied to the closed eyelid for 2 minutes. The degree of ptosis should be evaluated immediately after removing the bag of ice (7).

A more definitive test is a repetitive nerve stimulation study or single-fiber electromyography. In MG, there is a decrement in the amplitude of the evoked muscle action potential when the motor nerve is repetitively stimulated at 3 cycles/sec.

If the diagnosis of MG is confirmed further testing should include an assay for circulating anti-ACH receptor antibodies. A CXR, thyroid function tests, and serologic testing for associated autoimmune diseases should also be performed.

KEY TESTING

- Tensilon test or ice pack test

- CBC
- Electrolytes, calcium, magnesium, phosphorus, myoglobin, serum creatinine, and BUN

ED Management

The major focus of ED management of all disorders of neuromuscular transmission is ongoing evaluation of the patient's respiratory status. The maintenance of a patent airway may be difficult because of increased oral secretions and inadequate protective reflexes. Evidence of respiratory failure may be noted on ABG, pulmonary function tests, or pulse oximetry. Rapid sequence intubation should be modified because depolarizing paralytic agents (e.g., succinylcholine) have less predictable results in patients with myasthenia. The relative lack of ACH receptors makes these patients relatively resistant to succinylcholine; therefore, higher than usual doses of succinylcholine may be necessary to induce paralysis or one may use a nondepolarizing agent, such as rocuronium.

Once the airway is secured, investigation into the cause of the weakness or exacerbation of myasthenia may be undertaken. There are five major therapeutic options in managing patients with MG: anticholinesterases, immunosuppressives, thymectomy, plasmapheresis, and IV immunoglobulin (8).

Anticholinesterases are considered first-line agents for treatment of MG. Their primary action is to increase the concentration of ACH at the synapse. Pyridostigmine is the most frequently used agent in this class. Although the anticholinesterases provide symptomatic relief, they do not influence the progression of the disease. The initial dose of pyridostigmine is frequently 30 mg every 8 hours.

Immunosuppressive therapy is added to the medication regimen of patients whose symptoms are inadequately controlled by anticholinesterase drugs. Corticosteroids are the initial agent of choice followed by other agents such as azathioprine, cyclosporine, or mycophenolate mofetil, if steroids are contraindicated or ineffective.

Thymectomy is indicated in selected patients younger than 60 years of age who have the generalized form of MG and in those individuals who have thymoma (8). Randomized controlled trials evaluating the efficacy of thymectomy in MG are lacking; however, observational studies have noted patients who undergo thymectomy are twice as likely to show improvement.

Plasmapheresis and IV immunoglobulin (IG) are two short-term therapeutic options that are particularly useful when rapid clearance of antibody is required either to improve symptoms in myasthenic crisis or in patients in whom immunosuppressive treatment has been initiated. The recommended dose for IG is 2 g/kg over 2 to 5 days, and the improvement begins within 4 to 5 days following administration (9,10).

Some medications including anticonvulsants, neuromuscular blockers, some antibiotics, and major analgesics (Table 160.4) should not be administered in patients with MG. Acute intercurrent medical and surgical problems in patients with MG should always be managed in consultation with a neurologist (11).

TABLE 160.4
Common Drugs Capable of Impairing Neuromuscular Transmission or Exacerbating Weakness in Patients with Myasthenia

Antibiotics	**Psychotropics**
Aminoglycosides	Chlorpromazine
Ampicillin	Lithium
Clarithromycin	Phenothiazines
Clindamycin	**Analgesics/Muscle Relaxants**
Fluoroquinolones	Benzodiazepines
Anticonvulsant	Ketamine
Phenytoin	Lidocaine
Gabapentin	Narcotics
Cardiovascular	**Other Drugs**
β-Blockers	Glucocorticoids
Calcium channel blockers	Magnesium sulfate
Quinidine	Iodinated contrast agents
Procainamide	Statins

Myasthenic Crisis Versus Cholinergic Crisis

One of the confusing factors in treating patients with MG is rapid worsening of the disease caused by insufficient medication (i.e., myasthenic crisis) and side effects of excessive medication (i.e., cholinergic crisis) since they both have similar presentations. Cholinergic crisis results from an excess of cholinesterase inhibitors (i.e., neostigmine, pyridostigmine, physostigmine) and resembles organophosphate poisoning. Excessive ACH stimulation of striated muscle at nicotinic junctions produces flaccid muscle paralysis that is clinically indistinguishable from weakness due to MG. As a rule, in cholinergic crisis, worsening muscle weakness should be accompanied by symptoms of cholinergic excess, including salivation, lacrimation, urination, diarrhea, gastric distress (cramps), emesis, miosis, and bradycardia. Edrophonium can be a useful tool. This agent should make myasthenic weakness better and should exacerbate the cholinergic crisis. Unfortunately, edrophonium has limited use in an acutely decompensating patient. Therefore, it is recommended that all anticholinesterase medications be stopped in myasthenic crisis (11).

In practice, the distinction between myasthenic crisis and cholinergic crisis may not be very relevant, because initial

management does not involve the administration of cholinergic agents for the patient with myasthenic crisis.

Myasthenic crisis is a true emergency and usually requires respiratory support. Fifteen percent to 20% of myasthenic patients will experience at least one episode of myasthenic crisis (11). In the majority of patients with myasthenic crisis, an underlying precipitating event can be identified. Infection is the most common risk factor, followed by aspiration pneumonitis and changes in medication (especially initiation or withdrawal of corticosteroid). In 30% to 40% of the patients with myasthenic crisis, no precipitating factor can be identified (11). Management of the patient with myasthenic crisis requires general supportive measures and rapid reduction in anti-ACH receptor antibody load. Plasmapheresis is beneficial in myasthenic crisis, and improvement in the patient's clinical status can be seen within a few days. IV IG should also be considered. In a critically ill patient with a secured airway, high-dose steroid therapy should be initiated immediately. All medications that may impair neuromuscular transmission should be discontinued.

BOTULISM

Botulism is caused by a neurotoxin produced by the anaerobic organism *Clostridium botulinum. C. botulinum* toxin irreversibly binds to the presynaptic membrane and prevents release of ACH. A rapidly progressive descending paralysis follows and is accompanied by prominent, autonomic symptoms and respiratory involvement. Because the disorder is at the neuromuscular junction, there is no sensory deficit and no sense of pain.

Botulism may vary from a mild illness to a fulminant, fatal one. Cranial nerve findings in the presence of GI symptoms should alert the ED physician to the diagnosis of botulism. Prodromal symptoms of nausea, vomiting, diarrhea, and a dry, painful throat develop hours to days after ingestion of contaminated food. Neurologic symptoms are usually noted within 72 hours of ingestion and include anticholinergic effects (dry eyes, dry mouth, dilated pupils,

absent pupillary light reflex, ileus, and urinary retention) and fluctuating but rapidly progressive weakness, with early involvement of the extraocular and bulbar muscles (with ptosis, diplopia, dysphagia, and dysphonia as common early symptoms). The disease then progresses over several days to involve all the muscles of the trunk and extremities. Respiratory compromise can develop rapidly as the symmetric paralysis descends (12).

See Chapter 352, for detailed information on the clinical presentation and management of botulism.

LAMBERT&NDASH;EATON SYNDROME

Lambert–Eaton myasthenic syndrome is a rare autoimmune condition affecting the presynaptic membrane. Failure of neuromuscular transmission in Lambert–Eaton syndrome is caused by the insufficient release of a neurotransmitter at the presynaptic terminal. Antibody-mediated blockade of the voltage-gated calcium channel (VGCC) compromises rapid influx of calcium, which results in deficient neurotransmitter release.

Lambert–Eaton syndrome exists in a primary form but may be a manifestation of a paraneoplastic disorder. Malignancy is a common cause of rapidly evolving symptomatology in patients with Lambert–Eaton syndrome. The majority of patients with Lambert–Eaton syndrome are older than 60 years of age, but it has been described in all age groups.

The weakness in Lambert–Eaton syndrome is severe at the onset, but it improves soon after initiation of activity and then it deteriorates. Muscle weakness in Lambert–Eaton syndrome tends to be symmetrical and is most pronounced in the lower extremities. Altered gait after prolonged walking usually is the initial symptom. This weakness may progress to inability to rise from a chair or walk up stairs. Ocular and bulbar symptoms are not common and are mild in nature when present. Autonomic symptoms are common and occur in more than half of the patients. On physical examination, proximal muscle weakness is the most prominent clinical finding. The peculiar weakness in Lambert–Eaton syndrome patients may be

demonstrated during hand grip. The initial grip may be weak but gets stronger, only to weaken again (13).

The treatment for nonneoplastic cases of Lambert–Eaton myasthenic syndrome includes symptomatic therapies, such as 3,4-diaminopyridine, and immunologic therapies, such as glucocorticoids, azathioprine, IV IG, and plasma exchange. The neoplastic variant may respond to similar treatment; in addition, it requires treatment of the underlying malignancy (14).

TICK PARALYSIS

Tick paralysis is the result of envenomation from the gravid female tick and presents as an ascending flaccid paralysis or as an acute ataxia (15). In the United States, the disease occurs primarily in children during warmer months and is caused by the common dog tick (*Dermacentor variabilis*) or female wood tick (*Dermacentor andersoni*). The primary abnormality is in conduction in the peripheral nerves at the neuromuscular junction. The presentation is similar to Guillain–Barré syndrome. The presenting symptoms are ascending symmetric paralysis over 1 to 2 days, eventually involving the bulbar muscles. Ataxia may be present and may be the earliest finding. Sensory changes are rare, and DTRs are absent or decreased. The physician should perform a careful physical examination noting the presence and subsequent removal of the tick. The ticks are often found in the scalp, especially at the hairline. The removal is followed by prompt recovery. Unrecognized, the patient may progress to respiratory paralysis.

The definitive treatment for tick paralysis involves a careful examination for detection of the tick, and its removal.

DISPOSITION

Patients with severe weakness require admission to an intensive care setting for supportive care, monitoring of cardiorespiratory status, treatment of any underlying illness, and further diagnostic evaluation. Admission is indicated for patients with slowly progressive neuromuscular weakness if there is any concern about

the patient's respiratory reserve, if the degree of pharyngeal muscle weakness suggests a risk of aspiration, if rhabdomyolysis is suggested by CK determination and urinalysis, or if the patient cannot function satisfactorily at home. The decision to manage the problem on an outpatient basis must be made after consultation with the primary care physician, internist, or neurologist and on the condition that follow-up can be reliably arranged.

CRITICAL INTERVENTIONS

- Determine the need for intubation and mechanical ventilation by serial measurement of vital capacity. A declining vital capacity or a vital capacity <15 mL/kg is an indication for urgent intubation.
- Use a rapid-onset nondepolarizing agent (i.e., rocuronium, vecuronium) when paralysis is needed for intubating patients with MG.
- Perform a thorough search for an underlying precipitating illness in a patient with myopathy or MG who presents with an exacerbation.
- Perform a thorough search for a tick in patients presenting with new weakness.
- Obtain electrolytes on patients presenting with weakness.

Common Pitfalls

- Attributing a history of episodic weakness to neuroasthenia (psychogenic weakness) without considering the possibility of a neurologic disorder (e.g., periodic paralysis, MG, or multiple sclerosis).
- Failing to take a careful focused history in a patient presenting with a possible neurologic complaint.
- Failing to perform a thorough search for an underlying precipitating illness in a patient with myopathy or MG who presents with an exacerbation.
- Attempting an edrophonium test or other pharmacologic maneuvers in the acute management of myasthenic patients

presenting in crisis. Acute treatment involves attention to airway and ventilatory status with a low threshold for endotracheal intubation. Management decisions should be made in consultation with a neurologist.

- Prescribing medications that may exacerbate weakness in MG. Emergency physicians must be aware of drugs that can impair neuromuscular function. Treatment decisions should be made in consultation with a neurologist.

CHAPTER 161 Demyelinating Disease

Edward K. Lew and Don W. Penney

The term demyelinating disease is applied to a group of central nervous system (CNS) diseases that affect the myelin sheath but largely spare the axon. The major subgroups of demyelinating disease have been classified as follows: Group 1, demyelinating disease in which a disease process of exogenous origin affects and destroys normally formed myelin sheaths; and Group 2, dysmyelinating disease in which defective formation of myelin exists as a result of an inborn error of metabolism. This error of metabolism is usually a genetically determined enzymatic disturbance.

Multiple sclerosis (MS) is the most common autoimmune inflammatory disease of the CNS, affecting more than two million people worldwide. More than 400,000 people are affected in the United States. The disease occurs with an incidence of about 7 per 100,000 per year and a lifetime risk of 1 in 400. MS is a disease of young people, typically aged 18 to 50 years. MS is uncommon in children <10 years of age and usually presents before the age of 55. The onset tends to be earlier in women than in men. The female to male ratio is approximately 2:1. MS is more frequent in Caucasians of northern European origin and less common in Africans, Asians, and Mediterranean populations.

Although the cause of MS remains unknown, there appears to be an interaction between undefined environmental factors and genetic susceptibility to produce an inflammatory autoimmune response mediated by autoreactive T cells directed against components of myelin. Direct proof of an autoimmune cause is lacking, however,

and no specific autoantibody or autoreactive T cell directed against a self-antigen in the CNS can passively transfer MS to experimental animals.

The name *multiple sclerosis* speaks to the multitude of lesions throughout the CNS that have a sclerotic appearance on pathological specimens. Clinically, the manifestations of MS result from disruption and abnormal transmission of nerve impulses within the CNS by focal areas of demyelination.

MS is most often characterized by exacerbations of acute or subacute onset that last for days to months. Exacerbations are more commonly manifested by the reappearance of previous signs and symptoms than by the development of new ones. Recovery between exacerbations may be complete or incomplete. Relapsing, remitting disease refers to a situation in which the clinical course between exacerbations is stable. In general, a pattern of intermittent exacerbations is more common in the earlier stages of the disease, whereas progressive deterioration, with or without superimposed exacerbations, is more common in the later stages (secondary progressive course). A small percentage of patients experience disease progression from the onset, with or without superimposed exacerbations (primary progressive and progressive relapsing disease, respectively) (1).

CLINICAL PRESENTATION

The classic clinical picture of MS is that of multiple neurologic symptoms disseminated in space and time. The diagnosis of MS cannot definitely be made in the emergency department (ED). When symptoms first appear, they often develop steadily over days. Visual complaints often occur early. Symptoms such as blurring of vision, alteration in visual acuity and diplopia are common. Up to 40% patients with MS have optic neuritis, but up to 40% of patients with optic neuritis do not go on to develop MS. No single clinical feature or diagnostic test is sufficient for a final diagnosis, although some are relatively characteristic.

The diagnosis of MS continues to focus on objective demonstration of dissemination of lesions in time and space. This temporal perspective is generally unavailable to the emergency physician seeing the patient at only one point in time. In addition, diagnostic test results that enhance the confidence of a clinical diagnosis of MS are often not immediately available in the ED. Ultimately, the diagnosis of MS is a life-altering condition that imposes a significant psychological burden and should therefore not be made without a substantial degree of certainty.

The nature of the deficit depends on the anatomical location of the demyelinating lesion and its size and age (acute vs. chronic). The demyelinating process can also result in the generation of ectopic impulses, abnormal transmission of impulses between neighboring nerve fibers, and increased mechanical sensitivity. These phenomena are the basis for the generation of symptoms such as Lhermitte sign (an electric shock-like, tingling, or vibrating sensation in the torso or extremities that is produced by flexion of the neck against resistance), flashes of light on eye movement (phosphenes), and paroxysmal symptoms such as trigeminal neuralgia, ataxia, and dysarthria or painful tetanic posturing of the limbs triggered by touch or movement. Conduction in partially demyelinated axons fails with an increase in temperature, giving rise to characteristic worsening of symptoms with a rise in temperature as may occur with exercise or a warm bath (Uhthoff phenomenon) (1). Demyelination can occur anywhere within the CNS and the possible clinical manifestations of MS are therefore extremely varied. However, MS lesions have a predilection for certain sites, resulting in a relatively limited distribution of typical initial symptoms (2). Although no symptoms or neurologic findings are pathognomonic, some are characteristic and should heighten the clinician's diagnostic suspicions. The majority of patients present with one or more of the following signs and symptoms (see Table 161.1 for the common initial symptoms of MS).

TABLE 161.1
Common Initial Symptoms of Multiple Sclerosis

Visual loss
Paresthesias and numbness
Diplopia and oculomotor dysfunction
Weakness: monoparesis, paraparesis
Lhermitte sign
Incoordination, unsteady gait, abnormal balance
Acute transverse myelopathy
Vertigo
Bladder, bowel dysfunction
Tremor
Trigeminal neuralgia

Decreased visual acuity and symptoms related to oculomotor dysfunction are among the most common initial presenting symptoms of MS. Optic neuritis characteristically presents with subacute monocular loss of vision although simultaneous or sequential loss of vision can occur in both eyes. Visual loss typically progresses over days to 2 weeks and is accompanied by headache or retroorbital or periocular pain in most but not all cases that may be exacerbated by movement of the eye. Maximal loss of visual acuity varies from blurring to absence of light perception in the affected eye. Alteration of color vision and visual field defect may occur. Slit lamp exam is usually normal but occasionally may reveal cells and flare in the anterior chamber. The optic disc appears swollen on initial presentation in 36% to 58% cases. An afferent pupillary defect (Marcus Gunn pupil) consisting of diminished response to a direct light stimulus and a normal consensual response to a light stimulus in the opposite eye may be noted. Approximately 50% to 60% of patients with optic neuritis will have periventricular white-matter abnormalities consistent with demyelination on an initial magnetic resonance imaging (MRI) scan. Optic nerve involvement may remain as an isolated manifestation, but if demyelination is found on MRI as well, 72% of those patients will convert to MS

within 15 years, in contrast to 25% of those with a normal MRI (3,4).

Nystagmus and diplopia occur commonly in patients with MS. The finding of internuclear ophthalmoplegia (INO), especially in a young adult, is very suggestive. This form of dysconjugate gaze, localized to the medial longitudinal fasciculus (MLF) of the brainstem, involves limited adduction of one eye and nystagmus in the abducting eye on lateral gaze. Although there are other potential etiologies for INO, such as ischemia and neoplasm, these are much less common.

Sensory symptoms are among the most common presenting symptoms of MS and include numbness, tingling, pins and needles, tightness and coldness of the limbs or trunk. Radicular pain and itching in a dermatomal distribution can occur. Symptoms are variable in distribution and can be referable anatomically to the spinothalamic, posterior column and dorsal nerve root or can occur distally in the extremities or in a patchy distribution. Motor weakness may occur as paraparesis, hemiparesis, or monoparesis and is generally accompanied by signs of upper motor neuron dysfunction (e.g., hyperreflexia, hypertonia, and positive Babinski sign) (1). Transverse myelitis can be the initial neurologic event. Symptoms include ascending weakness and numbness below the level of the lesion.

The brainstem can be affected by MS plaques. Neuroanatomically, both ascending and descending tracts are found within the brainstem in close proximity. Corticospinal, corticobulbar, spinothalamic, lemniscal, vestibular and cerebellar tracts, and interneural pathway connections can be affected. Likewise, 11 of the 12 cranial nerves have either nuclei in the brainstem or synaptic connections within the brainstem.

Patients with Known Multiple Sclerosis

In most cases, the natural history of MS is characterized by episodes of neurologic dysfunction alternating with periods of stabilization or remission of symptoms. Common signs and symptoms of chronic

disease are listed in Table 161.2. Patients with known MS may present to the ED because of an exacerbation of previous deficits, because of the development of new deficits, or because of medical complications of the disease.

TABLE 161.2
Common Chronic Problems of Multiple Sclerosis

Problem	Drugs Used in Treatment
Weakness: monoparesis, paraparesis, hemiparesis, quadriparesis	Corticosteroids, potassium-channel blockers (i.e., 4-aminopyridine; 3,4-diaminopyridine)
Spasticity	Baclofen (oral or intrathecal), benzodiazepines, dantrolene, tizanidine
Paresthesias	Amitriptyline, carbamazepine, gabapentin, corticosteroids if disabling
Bladder dysfunction	Depends on type of impairment
Optic atrophy, blurred vision, central scotoma	Intravenous methylprednisolone for acute optic neuritis
Internuclear ophthalmoplegia, diplopia	Corticosteroids
Loss of balance, incoordination, ataxia tremor	Clonazepam for tremor, corticosteroids for balance
Cognitive changes	Disease-modifying agents (e.g., interferon beta, glatiramer acetate); assessment for depression
Depression	Antidepressants
Sexual dysfunction	Sildenafil, intracavernosal prostaglandins (for erectile dysfunction)
Fatigue	Amantadine, CNS stimulants
Vertigo	Meclizine, prochlorperazine, diazepam, metoclopramide
Paroxysmal symptoms: itching, burning, twitching, Lhermitte sign	Carbamazepine, phenytoin, tricyclic antidepressants, low-dose antipsychotics, gabapentin
Pseudobulbar palsy	Amitriptyline, levodopa, bromocriptine

Factors that have been cited as having an association with occurrence of MS exacerbations are infection (including minor respiratory infections and gastrointestinal infections), and the

postpartum period. Pregnancy itself has not been associated with an increase in frequency of attacks (1,5).

Common secondary complications in patients with MS are pneumonia, infections of the urinary tract, septicemia, respiratory failure, pulmonary embolism, bladder and renal calculi, and pressure ulcers of the skin (2). Elevated body temperature, occurring as a result of infection or because of exposure to heat, can be associated with a transient increase in neurologic symptoms (Uhthoff phenomenon). Exacerbations that include dysphagia can result in aspiration pneumonia.

Fatigue is a common complaint of patients with MS. It typically increases with exercise, heat exposure, or as the day progresses. Spasticity, a manifestation of upper motor neuron disease, is characterized by increased muscle tone, hyperreflexia, decreased mobility, painful muscle spasms, and weakness. There is conflicting evidence as to whether seizures occur more frequently in MS patients than in the general population. When seizures occur, they should not be attributed to MS until other causes have been ruled out. Similarly, aphasia and dementia should prompt a search for alternate causes.

Major depression has a lifetime occurrence of 50% in patients with MS. A recent critical review did not find adequate evidence to substantiate concerns that newer disease-modifying agents for the treatment of MS might be associated with an increase in the incidence of depression or worsening of depressive illness. Treatment of depression with usually psychotherapy and pharmacotherapy are often effective (6).

DIFFERENTIAL DIAGNOSIS

As previously noted, the diagnosis of MS is generally a clinical diagnosis that is made over a prolonged period of observation and is supported by laboratory and MRI data. There must be a minimum of two separate clinical episodes suspicious for an MS attack separated over a period of time with evidence of two separate CNS lesions. It is imperative that the diagnosis is made only after confirmation of

all data in support of the diagnosis and that all other potential diagnoses are ruled out. There is no single test that provides a definitive diagnosis.

The differential diagnosis of an acute neurologic deficit is broad and includes the intracranial and spinal cord processes listed in Table 161.3. Some of the more common diseases capable of causing multifocal CNS lesions disseminated over time are systemic lupus, Lyme disease, sarcoidosis, and CNS vasculitis. Because MS is a disease that is confined to the CNS, patients generally lack the rheumatologic and constitutional symptoms and laboratory abnormalities that are present in many of these other disease states. Spinal cord compression by mass lesions or hematomas must be considered in the patient who presents with symptoms referable to the spinal cord. The differential diagnosis of transverse myelitis includes both infectious (e.g., herpes simplex) and postinfectious causes. Optic neuritis may be caused by syphilis, demyelination following vaccination or viral infection, sarcoidosis, systemic lupus erythematosus, herpes zoster, and diabetes mellitus.

TABLE 161.3
Differential Diagnosis of Acute Focal Neurologic Deficit

Bleeding (Spontaneous or Traumatic)	**Vascular**
Subdural hematoma	Thrombosis
Intraparenchymal hemorrhage	Embolism
Epidural hematoma	**Metabolic**
Subarachnoid hemorrhage	Hypoglycemia
Infection	Hyperosmolar hyperglycemia
Abscess	Vitamin B_{12} deficiency (spinal cord)
Brain	**Miscellaneous**
Epidural	Postictal
Subdural	Migraine
Meningitis, encephalitis	Bell palsy
Neoplasm	Guillain–Barré syndrome
Primary	Psychogenic (diagnosis of exclusion)
Metastatic	

ED EVALUATION

The diagnosis of MS requires the demonstration of focal neurologic signs and symptoms scattered over time and space. When faced with a patient with one or more focal neurologic deficits in whom MS is suspected, a critical task of the ED provider is the exclusion of other disease entities that may mimic the diagnosis and require specific immediate treatment. The definitive diagnosis of MS is most appropriately left to the neurologist in the non-ED setting.

Just as no neurologic findings are pathognomonic for MS, no laboratory test is universally diagnostic. Diagnostic evaluations used to confirm the diagnosis in situations in which the diagnosis cannot be made definitively on clinical grounds include visualization of anatomic dissemination of lesions in time and space with MRI of the brain and spinal cord; assessment of inflammatory and immunologic dysfunction through cerebrospinal fluid (CSF) examination; and demonstration of alteration of conduction in a pattern consistent with demyelination through the use of evoked potentials (EPs) as outlined by the McDonald criteria for the diagnosis of MS (1,7,8).

MRI is the most sensitive and specific test used to make the diagnosis of MS (9). T2-weighted brain imaging is superior in sensitivity to contrast-enhanced computed tomography (CT). More than 90% of patients with MS have MRI abnormalities, but there are no findings that are entirely pathognomonic for MS. Because myelin has a relatively short T2 and T1 relaxation times due to its lipid content, normal myelin is hypointense to gray matter on T2-weighted images and hyperintense on T1-weighted images. In MS, there is a reduction in myelin content; as a result white matter becomes less hydrophobic and takes on more water. A decrease in myelin and an increase in water content prolong the relaxation times of both T1- and T2-weighted images, resulting in more signal on T2-weighted and fluid-attenuated inversion recovery (FLAIR) images, and less signal on T1-weighted images.

Characteristic lesions observed on MRI are plaques typically found in the periventricular region and juxtacortical white matter. MS plaques usually appear as discrete foci, ovoid in shape with well-

defined margins. Most are small and irregular, however some of these lesions can coalesce forming larger-sized lesions. Plaques correspond pathologically to multifocal areas of demyelination and perivascular infiltration of lymphocytes, macrophages, and plasma cells. Typical lesions are ovoid and are arranged like fingers radiating away from the walls of the lateral ventricles. In addition, lesions commonly involve the corpus callosum, white matter abutting the temporal horns, trigones of the lateral ventricles, brainstem, cerebellum and spinal cord. Signal enhancement with gadolinium is characteristic of the disruption of the blood–brain barrier that occurs with active inflammatory lesions. The number, size, and distinctive location of areas of increased signal found on MRI help distinguish MS from other neurologic diseases.

MRI is used to monitor the course of the disease and its response to treatment and is useful in identifying alternate diagnoses such as intracranial neoplasm, vascular abnormalities, and spinal cord lesions. A negative MRI does not, however, have sufficient sensitivity or negative predictive value to rule out the diagnosis (10). Diseases that may produce similar lesions include ischemia, systemic lupus erythematosus, Behçet disease, other vasculitides, human immunodeficiency virus (HIV), and sarcoidosis.

Findings on MRI are common in patients with optic neuritis, even when there is no other clinical evidence of MS. MRI has been demonstrated to have prognostic value in predicting conversion from isolated syndromes, such as optic neuritis, myelitis, and INO to MS (3,4).

CSF examination can help to confirm the diagnosis by demonstration of immune and inflammatory mediators of disease. For the diagnosis of MS, CSF abnormality is defined as the presence of oligoclonal immunoglobulin G (IgG) bands different from bands in the serum or the presence of an elevated IgG index (7,8). Oligoclonal bands may be present even when the total CSF IgG content is normal. Studies have shown very poor correlation between the presence of oligoclonal banding and the degree of MS-induced disability. Changes in CSF IgG patterns have found not to be specific for MS. Patients with infection of the CNS, both acute

and chronic, and brain neoplasms can also demonstrate changes in immunoglobulin levels. Other common CSF findings include elevated total protein and modestly increased mononuclear cell count (<50 cells/μL). In addition, CSF analysis permits the exclusion of infection as the cause of symptoms.

EPs are electrodiagnostic studies that measure the electrical potentials (voltages) that are evoked in response to the application of brief sensory stimuli. Demyelination causes abnormal axonal conduction that can be picked up on EP testing as abnormal potentials. In the past, prior to the development of MRI, visual evoked potentials (VEPs) were utilized in the diagnosis of MS. VEP often demonstrated a delay in conduction of visual responses from retina to occipital (visual) cortex. These studies were positive in 90% patients with clinically obvious MS. Both VEPs and somatosensory evoked potentials (SSEPs) may also detect subclinical sites of demyelination. This modality falls into the domain of the neurologist and is not part of the ED evaluation.

KEY TESTING

- Thorough neurologic examination
- MRI of brain to aid in initial diagnosis of MS
- Search for infection in patient with established MS
  - CBC
  - UA
  - CXR

ED MANAGEMENT

Treatment of acute exacerbations of MS is most appropriately undertaken in consultation with a neurologist. The anti-inflammatory effects of steroids have traditionally been the primary therapy for relapses in patients with known disease. Corticosteroids shorten the duration of relapses and their short-term morbidity but have not been demonstrated to alter the evolution of the disease or to prevent relapses (1,11,12). There are no rigid guidelines for the use of steroids, but protocols generally include high-dose IV

methylprednisolone, 1 to 2 g daily for 3 to 10 days, with or without an oral taper (12). For the rare patients who cannot tolerate corticosteroids or have had a prior poor response, intramuscular adrenocorticotropic hormone (ACTH) is an option. However, there is a significant incidence of weight gain, hypertension, and edema as compared with steroids (11).

A recent Cochrane review comparing different routes of steroid administration (i.e., IV vs. oral) failed to demonstrate a clear advantage of one over the other, giving weight to the notion that oral steroids are an effective alternative to parenteral steroids (13). An exception is in the treatment of optic neuritis. A recent meta-analysis concluded that corticosteroids did not result in an improvement in eventual return to baseline vision, but that IV corticosteroids did result in faster recovery. On the other hand, oral steroids appeared to be associated with more likely recurrences of optic neuritis. Thus, initial treatment with high-dose IV corticosteroids followed by oral formulations is thought to be reasonable (14).

If a relapse is deemed to be corticosteroid-refractory, plasmapheresis can be considered. It has recently been given a Class B recommendation from the American Academy of Neurology (12,15), but is not recommended for the progressive types of MS.

Current research has focused on two areas: (1) preventing disease burden from acute relapses, and (2) stabilizing MS in the long term. Interventions are aimed at suppressing inflammation, limiting demyelination, enhancing remyelination, and improving conduction in demyelinated fibers. As previously noted, some short-term treatments may accelerate recovery from relapses but do not prevent future relapses or eventual disabilities (16). Long-term management typically involves disease-modifying therapies (DMTs). Currently, there are at least eight DMTs approved for MS by the US and European drug-regulating bodies. Interferon-beta and glatiramer acetate are currently the most commonly prescribed agents. The annual relapse rate of patients treated with these drugs is lower than that in those treated with placebo by up to 30% (12,16). Interferon-beta also lowers the progression of disability; glatiramer

acetate has not been proven to do so. For the most part, interferons and glatiramer acetate are first-line MS treatments as they have a good safety profile, reasonable tolerability and efficacy, and low toxicity. Nevertheless, their use may be limited by adverse events (such as flu-like symptoms, depression, injection site necrosis, elevated liver enzymes, leucopenia, and anemia) and cost. As always, risk–benefit ratios have to be determined by both physician and patient. Other approved treatments with more potentially serious adverse effects are being studied, including natalizumab, fingolimod, dimethyl fumarate, and teriflunomide (7,16). Therapies currently under investigation include mitoxantrone, alemtuzumab, laquinimod, rituximab, daclizumab, and cladribine (7,16). Administration of disease-altering drugs generally is the domain of the neurologist.

In the patient with known disease who presents with fever, sources of infection should be sought and treated aggressively. Patients with bladder dysfunction are particularly susceptible to urinary tract infection; decubitus ulcers and pneumonia are other common sources of infection that should be considered. Antipyretics should be administered because of the Uhthoff phenomenon. An elevated temperature that is related to heat exposure should be treated by active cooling measures. Table 161.2 lists some of the more common fixed neurologic symptoms of MS along with their treatments.

CRITICAL INTERVENTIONS

- Do not make the initial diagnosis of MS in the ED.
- Initiate high-dose methylprednisolone in the treatment of optic neuritis.
- Diagnose and treat fever in MS patients because elevated body temperature, occurring as a result of infection or exposure to heat, can be associated with a transient increase in neurologic symptoms.

DISPOSITION

The patient with newly onset clinically suspected MS may warrant hospital admission to complete the diagnostic workup, to exclude other causes of signs and symptoms, and to undergo aggressive treatment of debilitating symptoms. For the patient with known MS, determination of the need for hospitalization depends on the general medical condition as well as the neurologic status. Patients may also require hospitalization for medical complications of MS (e.g., infection), for the administration of aggressive treatment of neurologic symptoms, and for the supportive care necessary because of disability during disease exacerbations.

Common Pitfalls

- Failure to identify and treat other disease entities in the patient with known or suspected MS.
- Failure to consider the possibility of intercurrent medical illnesses, especially those that commonly affect the chronically ill neurologic patient (e.g., urinary tract infection, pneumonia, decubitus ulcers).
- Failure to realize that rheumatologic or constitutional symptoms or abnormal laboratory values should call the diagnosis of MS into question.
- Making a diagnosis of MS in a patient with progressive disease at a single site (e.g., spinal) when other diagnoses have not been adequately excluded.
- Failure to consider MS in the young patient presenting with focal neurologic signs and symptoms. The presenting symptoms of MS can be vague and transient, and can seem bizarre. A psychogenic etiology remains a diagnosis of exclusion.

CHAPTER 162

Parkinsonism and Other Movement Disorders

Todd A. Taylor

Parkinsonism, or Parkinson syndrome, is a group of progressive degenerative central nervous system disorders characterized by cardinal motor signs of bradykinesia, tremor, rigidity, and postural instability. Idiopathic Parkinson disease (PD) is the most common cause of parkinsonism and accounts for 80% of cases. Secondary parkinsonism, from a host of disparate causes, constitutes the remaining 20% (see Table 162.1).

TABLE 162.1
Causes of Parkinsonism

Parkinson disease (PD)
Neurodegenerative processes
Multiple system atrophy (MSA)
Progressive supranuclear palsy (PSP)
Corticobasal degeneration (CBD)
Drugs—phenothiazines, butyrophenones, anticonvulsants
Toxins—Methylphenyl tetrahydropyridine (MPTP), carbon monoxide, manganese, rotenone
Trauma
Malignancy—lymphoma, glioma
Arteriosclerotic parkinsonism
Infections—epidemic encephalitis, von Economo encephalitis

The incidence and prevalence of parkinsonism and PD are increasing, reflecting the aging population, and are now afflicting 1 million in America (1–3). There does not appear to be a genetic predisposition for PD when the disease begins after age 50 years, although there may be one for early-onset disease (3). PD is more common in men than in women and appears to be more common in whites than in other groups (1). Both PD and secondary parkinsonism have increased morbidity and mortality rates compared with the general population (1,4,5).

Although the precise cause and pathophysiology of PD is not known, recent studies suggest inflammation, oxidative stress, and abnormal protein accumulation leading to cell death in the substantia nigra (6–8). Profound localized depletion of the neurotransmitter dopamine in the substantia nigra is the biochemical marker for the disease (9,10). The mainstay of therapy for PD is neurotransmitter replacement in the form of levodopa or dopamine agonists. Infections (von Economo pandemic of encephalitis lethargica), toxins (the designer drug methylphenyl tetrahydropyridine [MPTP], the pesticide rotenone) (7), and medications (phenothiazines) are known causes of secondary parkinsonism (Table 162.1).

In practice, the diagnosis of parkinsonism and PD is made on clinical grounds, but the ultimate diagnosis still rests with neuropathologic confirmation at autopsy (11). Neuroimaging is typically used to rule out other causes but is unrevealing in cases of PD. PD has distinct cellular degeneration of the substantia nigra with characteristic Lewy bodies (12). The various secondary parkinsonian syndromes show etiology-specific pathologic changes in the extrapyramidal system and the cortex of the brain. Precisely how the neurochemical and pathologic changes in parkinsonism result in dysfunction of the regulation of tone and motor activity is not completely understood (5). Advanced imaging techniques such as functional magnetic resonance imaging (MRI) and positron-emission tomography are contributing to a better understanding of functional anatomy (13).

CLINICAL PRESENTATION

Patients can present to the emergency department (ED) with complaints referable to undiagnosed parkinsonism or with complications of previously diagnosed illness. Emergent interventions are rarely needed for the disease itself. However, it is important to make the diagnosis as soon as possible because effective symptomatic treatment is available, and there is the possibility of slowing disease progression.

The clinical manifestations of parkinsonism develop insidiously and gradually. The four cardinal signs are resting tremor, bradykinesia, rigidity, and gait disturbance (14). Typically some combination of these, together with a good response to levadopa therapy, is used to make the diagnosis (14). Motor deficiencies are usually asymmetric. Rigidity may be present on flexion and extension of the extremities and neck, and "cogwheel" rigidity on passive extension of the elbow or circumduction of the wrist may be noted. There are two types of rigidity in PD. The "lead pipe" rigidity is an increase in resistance to passive movement (15). Cogwheel rigidity is described as a catching sensation throughout passive range of motion (15). Early on, ambulation is generally slow; short or shuffling steps (*marche à petits pas*), instability, and falls occur later. The classic tremor of PD is a 3 to 6 Hz distal resting tremor that increases in periods of anxiety. An essential tremor is often confused for the resting tremor of PD. An essential tremor is an action tremor occurring during intentional motion as opposed to the resting tremor of PD. The resting tremor of PD disappears during voluntary movement (1). Monotonous speech and decreased speech volume are other early features, and there is eventual development of drooling, dysphagia, and masked facies. Sensory findings are generally absent. The presence of early dementia and psychosis (unrelated to medicines), autonomic dysfunction (orthostasis), cerebellar findings, and supranuclear gaze palsy suggest one of the secondary causes of parkinsonism (5,11).

In patients with known PD, complications of therapy or a worsening of symptoms while on therapy is often the reason for

presentation to the ED. The so-called on–off phenomenon, sudden wide fluctuations in motor function, ranging in severity from dyskinesia to freezing, can be particularly troubling to patients. This is thought to correlate with fluctuating drug levels throughout the day. “Wearing off,” or loss of therapeutic effect, should prompt a reassessment of the medication regime and also confirmation that secondary parkinsonism has not been erroneously diagnosed as PD, as one of the ways to rule out PD is the nonresponse to dopamine therapy. Orthostasis, nausea, vomiting, and acute psychosis can be caused by various dopaminergic and anticholinergic agents. Differentiating disease progression from medication inadequacy or excess can be difficult but is an important part of ED management.

Other complications related to general motor disability (e.g., traumatic injuries caused by falls) are significant reasons for ED presentation. In addition, many older patients, the cohort most affected by parkinsonism, have multiple medical conditions that can be more difficult to manage in the setting of progressive parkinsonism.

DIFFERENTIAL DIAGNOSIS

The primary entities in the differential diagnosis of parkinsonism are idiopathic PD and secondary parkinsonism. To help distinguish PD from secondary parkinsonism on a clinical basis, Gelb et al. (11) have suggested specific diagnostic criteria for PD: bradykinesia, rigidity, and the asymmetric onset of resting tremor, all of which must have a substantial and sustained response to levodopa or dopamine-agonist therapy. The presence of postural instability, freezing phenomena, hallucinations, dementia, severe dysautonomia, or supranuclear gaze palsy within the first 3 years of disease presentation suggests a secondary form of parkinsonism (12). PD has a gradually progressive course; rapid progression strongly suggests another form of parkinsonism (12).

ED EVALUATION

The ED evaluation of a patient with clinical symptoms suggestive of parkinsonism consists primarily of a history and physical examination. For patients with new symptoms, clinical assessment is aimed at identifying patients with a clinical picture that is consistent with parkinsonism and parkinsonian syndromes. It should be noted that even neurologists, according to one study, make the correct diagnosis only 82% of the time (16). The focus of the emergency physician should not be to make the diagnosis but rather to recognize patients who have parkinsonism symptomatology and referring them to a neurologist. MRI is useful in the comprehensive evaluation of parkinsonism but rarely is indicated in the ED (17).

For patients previously diagnosed with parkinsonism, evaluation should focus on progression of disease, complications of medical treatment, and concomitant medical conditions.

ED MANAGEMENT

Strategies for the management of parkinsonism in the ED should be coordinated with the physician who will treat the patient for the long term.

For patients who are newly diagnosed with PD, treatment includes agents to alleviate disabling symptoms, as well as agents that are potentially neuroprotective. Table 162.2 outlines treatment options. Levodopa and dopamine agonists are the mainstay of symptomatic treatment. Levodopa, a dopamine precursor, is more commonly used for initial treatment. Carbidopa blocks the peripheral metabolism of levodopa, allowing lower doses of levodopa to be effective centrally. The levodopa–carbidopa combination drug (Sinemet) has thus become a mainstay of treatment. It is desirable to use the minimum amount of levodopa necessary to control symptoms, because the metabolism of levodopa is thought to contribute to an excess of oxyradicals in the substantia nigra, leading to further cell degeneration. For this reason, dopamine agonists are sometimes used instead of levodopa. These medications are not as effective as levodopa but avoid the associated theoretical increase in cell destruction. Moreover,

limiting the dose of levodopa reduces the drug's peripheral side effects (nausea, vomiting, and orthostasis) (10). Agents with neuroprotective effects (dopamine agonists, monomine-oxidase [MAO]-B inhibitors) are other common alternatives (6). The anticholinergic drug benzatropine is prescribed selectively for patients with tremor predominance. For those with severe disease refractory to medical management, deep-brain stimulation of the subthalamic nucleus or the pars interna of the globus pallidus has been shown to significantly improve motor symptoms, although this therapy does have inherent risks and limitations as well (18–20).

TABLE 162.2
Management of Parkinson Disease[a]

Medical

Dopamine Precursor

Levodopa is a precursor of the pathologically deficient dopamine, which is able to cross the blood–brain barrier; improves symptoms; and is most often used in combination with carbidopa

Side effects include dyskinesia, anorexia, nausea, vomiting, postural hypotension

Peripheral Dopa-Decarboxylase Inhibitor

Carbidopa is a peripheral dopa-decarboxylase inhibitor and decreases peripheral breakdown of levodopa, allowing lower-dose therapy

Side effects include exacerbation of central dopaminergic side effects when levodopa dose is not reduced sufficiently

Dopamine Agonist

Pramipexole/ropinirole is a nonergot-based dopamine agonist used as adjuvant to levodopa or as early primary therapy

Side effects include nausea, vomiting hypotension, sleepiness, hallucinations, confusion, and compulsive behavior

Bromocriptine is a dopamine agonist used as adjuvant to levodopa; decreases the dopamine requirement, thus allowing lower-dose levodopa therapy[b]; and also appears to decrease dyskinesias and "on–off" side effects

Side effects include hypotension, nausea, vomiting, constipation, fatigue, and hallucinations

Pergolide is a dopamine agonist used as adjuvant to levodopa; and is also used by some as monotherapy, particularly early in young-onset PD

Side effects include hypotension, nausea, vomiting, constipation, confusion, hallucinations, dyskinesias, and dystonias

Monoamine Oxidase-B Inhibitor

Selegiline is a MAO-B inhibitor thought to reduce the peroxide produced as MAO-B metabolizes dopamine[c] and may also have some therapeutic effect

Side effects include sleep disturbances, psychosis, agitation, confusion, and dyskinesias

Anticholinergic Drugs

Benztropine is a striatal muscarinic blocker and is useful in treating the tremor of PD

Side effects include typical anticholinergic symptoms and signs

Surgical

Electrical deep-brain stimulation

Posteroventral pallidotomy

Neural-cell transplantation

PD, Parkinson disease; MAO-B, monomine-oxidase-B.

[a]Dosing regimens are very individualized and should be coordinated with the patients' neurologist or primary physician.

[b]Khandhar SM, Marks WJ. Epidemiology of Parkinson's disease. *Dis Mon*. 2007;53(4):200–205.

[c]Lachenmayer L. Differential diagnosis of parkinsonian syndromes: dynamics of time courses are essential. *J Neurol*. 2003;250(suppl 1):I11–I14.

For patients with known PD, ED management is directed at recognizing the inadequacy or excess of the medication regimen and adjusting dosages accordingly. The “on–off ” phenomenon is thought to be caused by fluctuations in drug concentrations. Changing doses or dosing intervals and adding other antiparkinsonism agents should be done only after consultation with the neurologist. A sustained-release levodopa–carbidopa combination appears to reduce the total levodopa requirement, as well as variations in drug concentration (21). Medication excess may cause acute psychiatric and cognitive side effects, such as psychosis, hallucinations, delusions, agitation, and confusion. This may require a decrease in dopaminergic and anticholinergic medications and the initiation of antipsychotics (10). The peripheral side effects of excessive dopamine (nausea, vomiting, and orthostasis) can also be treated by reducing levodopa doses. There also appears to be a small chance that the discontinuation of dopaminergic therapy may cause neuroleptic malignant syndrome (NMS) (22). The symptoms of NMS closely mimic those of PD (i.e., confusion, rigidity, tremor), so the clinician should ensure that medications are continued on patients being admitted to the hospital. The treatment of NMS in this circumstance consists of administering bromocriptine and restarting the patient’s Parkinson medications. Optimizing the balance of various agents can be difficult and should be coordinated with the patient’s primary physician.

The management of the parkinsonian syndromes other than PD is generally less effective. Parkinsonism caused by prescription medications may improve with cessation of the implicated agent, but parkinsonism associated with prior MPTP use is not reversible. Symptoms of neurodegenerative parkinsonism can be managed with the same agents used for those of PD, but there tends not to be a sustained response to therapy.

For all parkinsonian syndromes, injuries from falls, infections (e.g., aspiration pneumonia), and concomitant medical conditions should be evaluated and managed as with other patients, keeping in

mind the limitations imposed by the patient's chronic level of functioning.

CRITICAL INTERVENTIONS

- Keep NMS on the differential for the decompensated Parkinson patients with medication noncompliance
- Coordinate all management strategies and medication changes of Parkinson patients with the patient's long-term physician

DISPOSITION

Whether the diagnosis of parkinsonism is being considered in the ED or the patient is being seen for complications of therapy or progression of symptoms, the patient's primary care physician or neurologist should be consulted. This assures continuity of care, which is essential to optimize the management of this chronic condition. Rarely is admission to the hospital or transfer to a tertiary care center indicated for parkinsonism itself. Complications such as sepsis or injuries from falls are more likely to be indications for inpatient management.

Common Pitfalls

- The diagnosis of parkinsonism may be missed in patients with vague complaints of dizziness, unsteadiness, or inability to walk, unless the signs are specifically sought on careful neurologic examination.
- The complex medical regimens for PD require precise modifications to maximize clinical benefit while minimizing side effects.

SECTION XVI
Psychiatric Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 163 Medical Clearance

Kerryann B. Broderick

One in eight or nearly 12 million emergency department (ED) visits in the United States, in 2007 were due to mental health and/or substance use disorders (1). Mental health-related ED visits increased 75% between 1992 and 2003 (2).

Before the patient can be transferred to a psychiatric facility or service, the emergency physician (EP) is responsible for identifying any significant medical condition. The term *medical clearance* (many would debate is not an accurate term of what we perform) was developed in the 1970s. Weissberg's 1979 article (3) describes the common scenarios in which EPs apply the concept of medical clearance: (a) the psychiatric patient found to have no physical illness, (b) a psychiatric patient with a known medical condition that is not currently impacting the psychiatric illness, and (c) the psychiatric patient whose acute medical issue has been treated and is now ready for transfer to a psychiatric facility.

There is a lack of standardized nomenclature in this area. The terms *organic disease* and *functional disease* are, perhaps, most frequently used. Organic disease denotes nonpsychiatric causes, and functional disease indicates a psychiatric cause. Defining a mental disorder as "organic," however, implies that a nonorganic or functional mental disorder is unrelated to physical or biologic factors or processes (4,5). In fact, many chemical neurophysiologic and genetic factors have been documented to be related to psychiatric disease. The terms "functional" and "organic" were eliminated from the DSM manuals and it now distinguishes mental

disorders due to medical conditions or secondary mental disorders from primary psychiatric conditions (6).

In fact, the role of EPs is to determine if the patient has a medical condition that is either (a) masquerading as psychiatric illness or (b) the one that needs treatment urgently before the patient can be treated by a psychiatric service/facility. The prevalence of physical illness among psychiatric patients appears to be dependent upon the population studied. One study specifically reviewing ED practice found that 80% of patients in whom medical disease should have been identified in the ED were documented as "medically clear" (7), whereas another study found "medical problems" in only 19% of ED patients (8).

CLINICAL PRESENTATION AND ED EVALUATION

Patients who require medical clearance may be separated into two general categories: those with a known psychiatric illness and those without a prior psychiatric diagnosis but presenting with abnormal behavior and thought. The clinical evaluation of these patients includes focused history and physical exam, directed laboratory and ancillary tests, and consideration of the care available by the receiving psychiatric facility or service. In January 2006, ACEP published a clinical policy guideline on many of the issues outlined in this chapter (9).

Important questions include time frame involved in the onset of symptoms and other events leading up to presentation. Obtaining history from patients and their perception of the current situation and using all other potential sources (emergency medical personnel, caretakers, and caseworkers) will ensure the most comprehensive and accurate history.

Psychiatric patients with substance abuse comorbidity have a significantly higher number of ED visits than those without substance abuse (10). A detailed history on medication use, recent changes, and noncompliance, both prescribed and not prescribed, are important as these frequently cause or contribute to psychiatric complaints, especially in the elderly.

Medical problems must be excluded or identified and treated appropriately. Infections, particularly central nervous system, cardiopulmonary, and urinary, can aggravate a patient's underlying illness. Questions regarding history of fever, weight loss, appetite, recent surgery, and trauma should be included.

When a patient presents with psychiatric symptoms but does not have a known psychiatric disorder, it is critical to differentiate primary psychiatric illness versus secondary psychiatric illness (medical etiology). Factors strongly supporting a medical cause include age older than 40 years with no prior psychiatric history, abnormal vital signs, recent memory loss, and clouded consciousness (5,11). Medical conditions may manifest with significant psychiatric symptoms. The differential diagnosis of medical conditions that can present with psychiatric symptoms is broad. Table 163.1 includes some of these conditions.

TABLE 163.1
Treatable Causes of Acute Mental Disorders Due to a General Medical Condition

Cardiac
- Dysrhythmias
- Congestive heart failure
- Myocardial infarction

Pulmonary
- Chronic obstructive pulmonary disease
- Pulmonary emboli
- Hypoxia

Hepatic
- Cirrhosis
- Hepatitis
- Wilson disease

Renal
- Worsening of mild nephritis by urinary tract infection
- Dehydration with elevation of BUN >50 mg/dL

Vascular
- Subdural hematoma
- Cerebrovascular accident
- Infection
- Vasculitis

Endocrine Disease
- Thyroid disease
- Cushing disease
- Diabetes
- Addison disease
- Hypoglycemia

Electrolyte Imbalance
- Hyponatremia
- Hypernatremia
- Hypercalcemia
- Hypoglycemia

Vitamin Deficiencies
- Thiamine
- Niacin
- Riboflavin
- Folate
- Ascorbic acid
- Vitamin A
- Vitamin B_{12}

Drug-induced
- Alcohol
- Tranquilizers
- Over-the-counter preparations
- Any drug used to treat medical illness (e.g., phenytoin, aminophylline, digitalis, steroids)

Exogenous Toxins
- Carbon monoxide
- Bromide
- Mercury

Lead
- Tumors
- Nonconvulsive status epilepticus
- Normal pressure hydrocephalus
- Depression

Multiple studies have documented that both emergency medicine and psychiatric physicians do a less-than-optimal job at documenting the physical examination (7,12). Psychiatrists surveyed reported completing a physical examination in only 13% of their inpatients, citing that they feel incompetent to do so (12). Therefore, it is very important that the EP perform a thorough search for evidence of medical illness that needs urgent treatment.

Two of the more frequent conditions encountered are delirium and dementia, and distinguishing between these two can be very important. Delirium is most often due to a medical condition and is an acute condition. Dementia is a more chronic condition. A mnemonic useful in rapid differentiation between delirium and dementia is COMA: *c*onsciousness, *o*rientation, *m*emory, and *a*ffect. Patients with dementia should have no significant alterations in these areas. The vital signs and a mini-mental status exam also help to distinguish between these two conditions (see Chapter 152).

Ancillary testing is a matter of great debate in the literature. Some facilities require mandatory testing, whereas others rely on their EP's judgment. Parmar and others studied 598 patients prospectively and found that after cleared by the EP, psychiatry ordered lab or radiographic testing on 44% of patients transferred and only 0.5% had an abnormal result which led to a disposition change. The total reimbursement for this added testing was $37,682 (13). Most would agree that a thorough history and physical will guide most clinicians in indicated ancillary testing. Studies have demonstrated that where history is obtainable, patient self-reporting on medical symptoms has a 94% sensitivity of predicting disease (8).

Although there is no consensus from the literature on laboratory testing, there are some useful guidelines. New-onset psychiatric complaints may signal the need for more extensive testing for a medical etiology (14). Routine testing in patients older than the age of 40, especially in the geriatric population, may have a higher pretest probability for significant positive results that either

demonstrate the etiology of the symptoms to be medical or signal the need for urgent treatment prior to medical clearance (15–17).

Clinicians should order focused testing (Accu-Chek, complete blood count, electrolytes, thyroid studies, urinalysis, toxicologic screen) based on history, physical exam, and vital signs. Alcohol levels and toxicologic screens may be useful in cases wherein the role of these substances in the patient's altered mental status is not clear.

A head computed tomography (CT) is warranted for patients with altered mental status or abnormal findings on neurologic exam. However, the decision to perform a head CT on patients with new psychiatric illness is less clear. In one study, abnormal head CT findings were found in 8% of 100 consecutive alert patients with psychiatric illness, but it was not clear that these findings were contributing to the patients' acute psychiatric illness (14).

DIFFERENTIAL DIAGNOSIS

Medications may be an important source of acute psychiatric symptoms. Anticholinergics, sympathomimetics, and serotonergics may be the etiology of a patient's altered thoughts. Patients taking stimulants such as cocaine, methamphetamines, and PCP may also exhibit psychosis. Common withdrawal syndromes associated with acute psychiatric features include alcohol withdrawal, particularly delirium tremens.

Elderly patients are particularly susceptible to toxic effects of medications owing to polypharmacy, dosing errors, and altered metabolism. If a medication is identified as the precipitant, clear instructions for dosing changes or drug substitution must be communicated with caregivers.

Thyroid diseases may be the etiology of acute psychiatric symptoms. Thyrotoxic patients may appear manic, delusional, or confused. Extremes in glucose can cause profound mental status changes. Those with adrenal disease are also susceptible to profound behavioral changes, which may mimic psychiatric symptoms. See Table 163.1 for additional causes of acute mental disorders.

KEY TESTING

- Focused testing based on history, physical examination, and vital signs
- glucose
- complete blood count
- electrolytes, BUN, creatinine
- thyroid studies
- urinalysis
- toxicologic screen

ED MANAGEMENT

Extreme agitation is often part of the syndrome of delirium or psychiatric disease and can significantly interfere with evaluation. Chemical restraint (CR) is a safe and effective method for controlling agitated or overtly violent patients (18,19). CR is accomplished by administering a standard dose of a high-potency antipsychotic medication, such as haloperidol or droperidol, in 5- to 15-minute intervals. Research indicates that the combination of antipsychotic medication with lorazepam is more effective than either medication alone, though the synergistic effects may cause excessive sedation (18–20) (see Chapter 167).

CRITICAL INTERVENTIONS

- Perform a thorough search for evidence of medical illness that needs urgent treatment.
- Distinguish between delirium and dementia.
- Control agitated or overtly violent patients with rapid tranquilization when indicated.

DISPOSITION

Some psychiatric facilities require toxicology tests, blood alcohol levels, or various ancillary tests to be done before they accept patients in transfer. Although some studies have shown that most patients accurately self-report drug use (21), and although

toxicology results usually do not impact the ED care, psychiatrists may find this information useful in their treatment of the patient (8). Shah et al. recently published a screening tool (22) that was modified from the one Zun previously developed (23). Psychiatry service ordered subsequent testing in 2.5% of those "cleared," of which none of these required any alteration in disposition or urgent treatment (22). The development of guidelines and protocols and a system for assuring that they are routinely reviewed and updated are essential to both patient safety and cost control.

Hospital admission is clearly warranted for patients with identified medical illnesses that are associated with a risk of morbidity or mortality. Hospital admission is also necessary if the patient's behavior jeopardizes further medical evaluation or care. Patients with delirium should be admitted for specific treatment if the cause is known or for further evaluation if the cause is unknown, with psychiatric consultation as needed.

Patient care may be transferred to a psychiatric service if an appropriate medical screening examination has been performed and it has been determined that the patient does not require further evaluation or treatment for an underlying medical condition, or for a medical condition that may be causing or exacerbating psychiatric symptoms.

Common Pitfalls

- Delirious patients who present to the ED are often inappropriately referred to a psychiatrist. This is especially true for those who present with bizarre and agitated behavior.
- Psychiatric patients who behave in a bizarre or disruptive manner may not be approached with the same sense of urgency or seriousness as are patients with cardiovascular disease or trauma. Clinicians often medically clear these patients without conducting a complete and thorough evaluation.
- Like disordered perception, the patient etiology that results in patient violence is often unclear, and these patients are often referred to a psychiatrist. A significant proportion of violence

that occurs in psychiatric settings results from underlying medical illness or drug intoxication (24).

- Clinicians often fail to take seriously the complaints of elderly patients, commonly attributing their symptoms to "old age" (16,25). Premature labeling tends to preclude the exhaustive physical, neurologic, and laboratory evaluation necessary to identify potentially reversible causes of dementia or delirium.

CHAPTER 164

Depression and Suicidal Ideation

Robert S. Hockberger and Joseph Ravera

Depression is the most common psychological disturbance affecting humankind: data from 2005 estimated a lifetime prevalence of 13% for the US population (1). Similarly, a 2006 Centers for Disease Control survey of over 200,000 US adults found that 9% met the diagnostic criteria for major depressive disorder (2). Suicide, the most notable sequela of depression, is the 11th most commonly reported cause of death in the United States, accounting for approximately 35,000 deaths annually (3). The number of annual suicide deaths is likely underestimated and may actually approach 100,000 (4). A 2003 audit of US workers found that depression costs employers approximately $44 billion per year in lost productivity (5).

Patients frequently seek nonpsychiatric medical care shortly before committing suicide. Up to 45% of those who commit suicide have visited a physician in the months prior to their death (6). It may be difficult for physicians without formal psychiatric training to recognize and evaluate depression and suicide potential, because many patients do not complain of depression or readily admit to suicidal ideation unless specifically questioned (7,8). Emergency physicians (EP) are further hampered by the hectic environment of the emergency department (ED), constantly changing priorities that limit one's ability to spend significant time with individual patients, and difficulty in obtaining after-hours psychiatric consultation. Nevertheless, the EP's ability to make these assessments and to

decide when to seek urgent psychiatric referral or hospitalization for potentially suicidal patients is a vital link in the effective management of a highly disabling and often fatal affliction. A 2001 US Public Health Service report emphasized the vital role of the ED in enhancing suicide-prevention efforts and recommended that guidelines be developed for the assessment of suicide risk among persons receiving care in the ED by 2005 (9). Although several scoring systems and clinical prediction rules are available, there are still no universally accepted guidelines for the determination of suicide risk.

CLINICAL PRESENTATION

Depression and suicidal ideation generally present in one of two ways. Most commonly, patients present overtly with chief complaints of suicidal ideation, request for psychiatric help, or following suicide attempts. Alternatively, depressed patients may present with occult complaints, most commonly multiple vague, ill-defined somatic symptoms such as weakness, malaise, weight loss, headache, and back pain; however, a thorough medical evaluation should be made before attributing such physical complaints to a psychological cause. Depressed individuals frequently have low self-esteem; loss of interest in or lack of enjoyment of previously pleasurable activities; depressed mood; loss of energy; poor appetite and weight loss (weight gain less often); sleep disturbances, including insomnia or hypersomnia; decreased attention span and ability to concentrate; decreased productivity at school, work, or home; episodes of tearfulness or crying; irritability or excessive anger (particularly in adolescents); feelings of hopelessness and worthlessness with a pessimistic attitude toward the future; and recurrent thoughts of death (7).

The potential for suicide should be considered in the following groups of patients:

1. Patients who have made a recent suicide attempt or have experienced recent suicidal ideation. Although most completed suicides involve firearms, drug overdose accounts for 70% to

90% of all suicide attempts (10). Major and minor tranquilizers and antidepressants have replaced barbiturates and other sedatives as the major agents involved in intentional overdose.

2. Patients who state that they are depressed or who complain of symptoms of depression.
3. Patients who present with problems related to chronic alcoholism, drug abuse, or any psychiatric disorder (particularly affective disorders, psychosis, and panic attacks).
4. Patients who present with apparently unintentional overdoses, self-inflicted gunshot wounds, lacerated wrists, falls from heights, or motor vehicle accidents of unclear cause (i.e., one-car, one-victim accidents in clear weather).

In some settings, a triage nurse may provide an initial screening assessment of suicide risk on selected or all patients presenting to the ED. When this occurs, communication of positive results with subsequent providers is critical to assure further evaluation and appropriate care.

DIFFERENTIAL DIAGNOSIS

A number of psychiatric and medical disorders may present with symptoms of depression. Approximately 80% of people suffering bereavement have one or more symptoms of depression for 1 year or more following the death of a loved one (10). Persons suffering from an adjustment disorder may develop similar symptoms within several months of the onset of psychological stresses (e.g., economic loss, physical illness, or troubled interpersonal relationships) with which they are unable to cope. The diagnosis of organic affective syndrome is made when symptoms of depression are found to accompany organic neurologic disease such as organic brain syndrome, stroke, tumor, or trauma. Symptoms of depression may be exacerbated or even caused by medications, including antihypertensive drugs (β-blockers, clonidine, methyldopa, and reserpine), antidepressants, antihistamines, neuroleptic agents, sedative hypnotic drugs, cimetidine, and alcohol (11).

When these diagnostic possibilities have been eliminated in a patient exhibiting symptoms of depression, a final diagnosis of dysthymic disorder (depressive neurosis or minor depression) or major affective syndrome (major depressive disorder) should be considered. This difference is one of degree, with each of these disorders falling somewhere on the disease spectrum of depressive illness, and the final diagnosis is best left to a psychiatrist.

ED EVALUATION AND MANAGEMENT

The clinical assessment of depression and suicide risk is an art as well as a science. Patients feel more at ease speaking about difficult personal issues when health professionals exhibit a friendly, nonjudgmental, supportive attitude and convey their willingness to listen. However, several studies have shown that many health professionals do not display these qualities, particularly ED staff. Reasons cited for this situation include inadequate time and staffing, patient behavior that is perceived as either abusive or manipulative, value conflicts, and staff frustration regarding ineffective disposition and follow-up options (12,13). Expression of a negative or hostile attitude by a respected authority figure, such as a physician or nurse, reinforces a depressed patient's feeling of diminished self-worth and may increase the likelihood of another suicide attempt.

Overtly depressed and suicidal patients are not very diagnostically challenging, but covertly suicidal patients presenting solely with somatic complaints can pose a diagnostic dilemma. Subtle presentations of a psychiatric problem may include midnight visits for minor complaints, multiple nonspecific somatic complaints involving many organ systems, unusual patient requests, indications of difficulties at home (particularly domestic violence), and trauma of unclear etiology. These potentially "silently suicidal" patients should be assessed in a sympathetic but direct manner.

Studies evaluating the utility of questionnaires and scales used to assess patients for depression in the outpatient setting have shown a wide range of sensitivity and specificity and many are cumbersome to use (14). In general, a stepwise approach should be used when

approaching patients who may have occult depression and may be silently suicidal. First, the presenting complaint should be addressed by asking general questions about the patient's home, work, and social situations. These general questions should be followed by specific questions regarding the signs and symptoms of depression. Finally, the physician should ask direct questions regarding suicide, such as these:

"Have you ever felt so bad that you thought about killing yourself?"

"Do you have thoughts of harming yourself now?"

"What plans have you made to do this?"

Physicians should not be reluctant to ask patients directly about suicidal thoughts from fear that doing so might bring to the surface subconscious thoughts of suicide and result in suicidal behavior. There is no evidence to support this concern; to the contrary, most depressed patients are relieved by the opportunity to openly discuss their problems when the clinician demonstrates an interest and a willingness to listen.

The main objective of the ED management of markedly depressed and suicidal patients is protecting them from further self-harm while performing an assessment and arranging for appropriate disposition. Suicidal patients must be kept under constant observation by a staff member and should be accompanied at all times, including restroom visits. Patients must be searched for medications and weapons and placed in a quiet area of the ED that is free of potentially harmful objects. No potentially suicidal patient should be allowed to leave the department before an evaluation is completed. All states have statutes permitting physicians to detain individuals deemed to be dangerous to themselves or others. Mechanical restraints should be used only when necessary to protect the patient or healthcare providers. The reasons for using restraints and the manner of restraint must be documented in the medical record. Restrained patients must be rigorously monitored and evaluated for complications. Chemical restraints such as intramuscular haloperidol or lorazepam may be required for patients who remain

agitated or violent, but these agents can impair psychiatric evaluation and should be avoided when possible.

Following the medical management of a patient's overdose, injury, or associated medical problems, the patient's degree of depression and potential risk for suicide should be assessed. Many studies have attempted to identify patients at high risk for suicide. Although no combination of clinical characteristics has been found that accurately identifies all patients likely to complete suicide, a number of high-risk characteristics have been determined. For example, a young woman who takes a few aspirin as a suicide gesture after fighting with her boyfriend is at less risk for successfully committing suicide than an elderly man who tries to hang himself on the anniversary of his wife's death. Most patients fall somewhere between these two extremes, and estimating a particular individual's risk for suicide is often difficult (11,15,16). Adding to this challenge for EPs is the fact that potentially suicidal patients often present at night and on weekends when psychiatrists are not readily available for consultation.

There is added difficulty in rural settings. Although depression rates are similar in urban and rural areas, studies indicate a higher rate of suicide in the latter, thought to be related to greater social isolation and lethality of method (firearms) in rural populations (17,18).

EPs should follow guidelines and protocols for suicidal risk assessment developed for their particular practice setting. Consultation may be provided by an on-call psychiatrist, by a psychiatric emergency team (PET) staffed by trained psychiatric nurses or social workers, by a patient's private physician or by the on-call primary care provider. EPs should be familiar with their state or county's policy regarding patients who have been placed on emergency psychiatric holds in the prehospital setting. In some areas, these holds mandate a psychiatric evaluation before they can be rescinded.

There are no studies demonstrating that hospitalization of high-risk patients prevents further suicide attempts or completed suicides. This lack of evidence, combined with national trends

toward providing more cost-effective outpatient treatment regimens, may place the busy EP in the position of making disposition decisions with high medicolegal risk.

The vast majority of patients attempting suicide do not go on to successfully complete suicide, which has led numerous investigators to develop and test a large number of clinical rating scales to predict suicide risk (19). Several studies have looked at screening tools to assess depression and suicide risk in ED patients (20–23). The modified SAD PERSONS scale (MSPS) has been used in the ED setting to guide the decision to admit patients based on suicide risk. The SAD PERSONS mnemonic incorporates several high-risk characteristics, which can help the clinician assess potentially suicidal patients (Table 164.1) (24,25). In one study, for nonintoxicated patients whose history can be corroborated by family or friends, the numerical SAD PERSONS score correlated closely with the need for hospitalization as determined by a psychiatrist. In this study, hospitalization was deemed necessary in almost all patients with a high SAD PERSONS score (>8), in approximately half of patients with intermediate scores (6 to 8), and in almost none of the patients with low scores (<6). The authors concluded that patients with an MSPS of <6 can be safely referred for expedited outpatient psychiatric evaluation, but a score of 6 or greater required emergent psychiatric evaluation and often hospitalization (sensitivity of 94% and specificity of 71%) (24). A more recent study prospectively evaluated six clinical rating scales, including the MSPS. The outcome variable was eventual admission based on a psychiatrist's assessment of suicide risk. In this study, all six scales had 100% sensitivity for identifying patients requiring hospitalization. This confirmed the usefulness of the MSPS in the emergency setting. The remaining five scales were just as sensitive but were more complex and less practical for use in the ED (15). Although the MSPS is a rapid and convenient tool to help organize, document, and communicate the assessment of a patient's suicide potential, a low score (<6) should not preclude emergent psychiatric consultation when the physician is uncomfortable with his or her assessment or when the patient requests to see a

psychiatrist. Strict cut-off scores alone should not be used to dictate consultation and admission to the hospital.

TABLE 164.1
SAD PERSONS Score

Factor	Description	Points
S = Sex	Male	1
A = Age	<19 or >45 yrs	1
D = Depression or hopelessness	Admits to depression or decreased concentration, appetite, sleep, libido	2
P = Previous attempts or psychiatric care	Previous attempt or previous inpatient or outpatient psychiatric care	1
E = Excessive alcohol or drug use	Stigmata of chronic addiction or recent frequent use	1
R = Rational thinking loss	Organic brain syndrome or psychosis	2
S = Separated, divorced, or widowed	Recent or on anniversary	1
O = Organized or serious attempt	Well-thought-out plan or life-threatening presentation	2
N = No social supports	No close family, friends, job, or active religious affiliation	1
S = Stated future intent	Determined to repeat attempt or ambivalent	2

SCORE

Score	Risk
<6	Low
6–8	Intermediate
>8	High

CRITICAL INTERVENTIONS

- Assess for depression and suicidal potential in patients with psychiatric disorders including substance abuse, in patients with multiple nonspecific somatic complaints, in victims of domestic violence, in patients with apparently unintentional overdose, and in victims of trauma of unclear etiology.

- Document your assessment in a consistent and standardized method; the modified SAD PERSONS scale is one approach that has been validated in the ED setting.
- Monitor potentially suicidal patients carefully in the ED; whenever possible, use patient sitters and avoid the use of restraints.

DISPOSITION

Potentially suicidal patients generally require hospitalization and admission to an inpatient psychiatric unit. Discharge from the ED should not be considered unless the following conditions have been met:

- The patient's injuries or associated medical problems do not necessitate hospitalization.
- The patient states that he or she is no longer suicidal and is not intoxicated, demented, or psychotic. Patients should be directly asked about the presence of auditory hallucinations and must be specifically assessed for signs of psychosis.
- The acute precipitant of the crisis has been identified, addressed, and resolved.
- The patient has cooperated with an evaluation and is deemed to be at very low risk for suicide. In general, nonpsychotic younger patients whose attempts involve low risk, high likelihood of rescue, and high manipulative intent can be discharged safely.
- Psychiatric consultation has been obtained (at least by telephone), and hospitalization is judged unnecessary.
- Short-term outpatient follow-up (within 1 to 2 days) has been arranged. The reliability of such patients in keeping follow-up appointments is poor. When ED personnel demonstrate a positive, supportive attitude and the patient is given a scheduled outpatient follow-up appointment at the time of discharge, patient compliance with follow-up improves markedly (26,27,28).

- The patient agrees to return to the ED immediately if further self-destructive urges arise.
- A positive, supportive environment with family or friends is available into which the patient can be released. Arrangements should be made to ensure removal of all pills, poisons, and weapons, especially guns, from the home.

A potentially suicidal patient should not be transferred to another facility or to a psychiatrist's office unless accompanied by medical personnel or family members who agree to deliver the patient and maintain close observation of the patient during transport.

Common Pitfalls

- "Accidental" trauma may be a manifestation of suicidal behavior. When the stated mechanism of injury is questionable or inconsistent with the injury seen, a more in-depth evaluation of the patient's emotional state and motives is warranted to screen for depression and suicide risk.
- Information obtained from a potentially suicidal patient must be corroborated with family or friends. Patients who vehemently deny suicide intent, refuse to answer questions, give abrupt answers to questions, or appear anxious to leave the ED may be committed to finishing the act they began.
- Anxiolytics, antidepressants, or any other potentially lethal medication should not be prescribed to patients who are depressed or potentially suicidal. More than half of patients who die by intentional overdose use a single prescription drug (9).

CHAPTER 165 Anxiety Disorders and Panic Attack

James A. Comes, Douglas A. Rund, and Basheer Lotfi-Fard

Anxiety is a common complaint of patients who present to emergency departments (ED). It is a nonspecific symptom that has diverse causes and clinical manifestations. Anxiety can be the chief complaint of a patient with a primary anxiety disorder, but often it accompanies a comorbid medical disorder. It is important for the emergency medicine physician to recognize an underlying emergent medical disorder in the anxious patient and be able to diagnose those patients in whom anxiety has become a pathologic condition (1).

CLINICAL PRESENTATION

Subjectively, the anxious patient feels a sense of worry, apprehension, and nervousness often accompanied by physical symptoms that reflect sympathetic activity (e.g., palpitations, sweating, dry mouth, dizziness, paresthesia, and faintness). Anxiety is a pathologic condition when the patient's physical and emotional responses surpass the normal response to a perceived threat and interfere with optimal functioning (2).

Clinically significant anxiety that is not associated with general medical illness, substance use, or substance withdrawal may warrant diagnosis of a primary anxiety disorder. Anxiety may be a feature of almost any psychiatric condition and is often prominent in schizophrenia, other psychotic disorders, depression, and bipolar

disorders. The emergency physician should have a general understanding of the clinical characteristics of all major psychiatric disorders, their chronic modes of treatment, and the ED assessment and management of acute presentations.

Panic attacks are extremely distressing experiences that often lead to ED visits. As many as 20% to 44% of patients with chest pain who come to the ED have a panic disorder (3,4). Recent surveys of the adult US population report an annual prevalence rate of 1% to 2% and a morbid risk (lifetime risk) of 2% to 4%. These episodes are abrupt, almost paroxysmal, in onset and progress rapidly to a degree of anxiety grossly disproportionate to any perceived threat or danger. The total duration is usually 10 minutes or less and almost never as long as 30 minutes. Following cessation of the acute episode, patients typically experience considerable residual anxiety centered on concerns about possibly having a life-threatening illness. Some patients describe their first panic attack as the worst experience of their lives.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of panic attacks depends on the specific circumstances in which they occur. Situational or cued panic attacks occur in association with particular experiences or stimuli, which may be internal or external, recognized or unrecognized. Uncued panic attacks are experienced as occurring “out of the blue” and are especially frightening because of the assumption that they are a symptom of life-threatening illness. The only psychiatric condition in which uncued panic attacks occur is panic disorder.

Most medical conditions are associated with some degree of anxiety, but certain conditions can be present with anxiety as a predominant feature. Examples include asthma exacerbation, hypoglycemia, pulmonary embolism, myocardial infarction, mitral valve prolapse, paroxysmal atrial tachycardia, thyrotoxicosis, pheochromocytoma, and carcinoid syndrome (5). In addition, anxiety itself may exacerbate a medical comorbidity because its associated symptomatic responses create demands on previously

impaired organ systems (6). Panic attacks may also be associated with substance use (caffeine or stimulants) and withdrawal (alcohol, barbiturates, or benzodiazepines). After these conditions have been ruled out, psychiatric diagnoses should be considered.

In phobic disorders, panic attacks may occur in connection with the unreasonable degree of fear associated with a particular stimulus or situation that the person makes effort to avoid. In acute and posttraumatic stress disorders, panic attacks may be triggered by environmental reminders, distressing memories, or flashbacks of the traumatic experience. In obsessive-compulsive disorder, panic attacks may be caused by situations in which the person fears being overwhelmed by the obsessional concern (7).

ED EVALUATION

It is critical to exclude a primary or comorbid medical disorder in the initial and ongoing assessment of patients with anxiety (8). Anxiety and depressive disorders are common among patients presenting with chest pain. However, the prevalence of anxiety and depressive disorders may be similar in patients with chest pain of cardiac and noncardiac origin (9).

Because of their inherently short duration, most panic attacks are clinically evaluated only retrospectively. Patients commonly seek emergency medical care following these upsetting experiences, especially if the attack was uncued. By the time they are examined, vital signs usually have returned to baseline. Even during the actual attacks, objective physiologic changes may be far less impressive than the degree of distress suggests. Panic attacks are brain events, and any peripheral changes are secondary manifestations. They are clinically recognized from the description of the person's internal experience, not from externally observable characteristics.

ED MANAGEMENT

Reassurance is the first-line intervention in patients with anxiety disorders. Patients should be assured that they are safe and will

receive help. A firm, direct approach in a quiet, comfortable environment helps the patient feel secure and in better control (10).

If a supportive interview is unsuccessful, pharmacologic intervention may be considered. Benzodiazepines can be used to treat acute anxiety. Collectively, benzodiazepines are similar in their clinical effect, although they differ in pharmacokinetic properties. Short-acting benzodiazepines with a rapid onset (half-life: 5 to 20 hours) include lorazepam (Ativan) and alprazolam (Xanax). For patients with history of substance abuse, hydroxyzine (Atarax, Vistaril) may be considered a useful alternative over benzodiazepines (11).

Once a diagnosis of panic attack is established, the patient should be reassured the panic attack is not imminently life-threatening. There may be serious long-term consequences if left untreated, and treatment options as an outpatient should be discussed (e.g., cognitive behavioral therapy or use of selective serotonin reuptake inhibitors).

CRITICAL INTERVENTIONS

- Assess patients with panic attacks for suicidal ideation, because there is a high rate of depression in these patients (12).
- Administer short-acting benzodiazepines for acute anxiety.

DISPOSITION

Most patients with anxiety disorders can be discharged from the ED with primary care or psychiatric follow-up. Patients who are actively suicidal, violent, or significantly disabled by their anxiety should be admitted to the hospital. Likewise, when the cause of acute anxiety is unclear, short-term admission for further medical and psychiatric evaluation should be considered. If benzodiazepines are prescribed, only a small quantity should be given, and close follow-up and subsequent psychiatric evaluation should be arranged.

Common Pitfalls

- Assuming that an acutely anxious patient, even one known to suffer from an anxiety disorder, has no medical problem. Patients presenting with anxiety must be presumed to have a medical condition as the cause until it is ruled out by an appropriate evaluation.

CHAPTER 166

Schizophrenia and Bipolar Disorder

James A. Comes, Douglas A. Rund, and Basheer Lotfi-Fard

CLINICAL PRESENTATION

Schizophrenia

Schizophrenia is a devastating mental illness characterized by psychosis, apathy and social withdrawal, and cognitive impairment, which results in impaired functioning in work, school, interpersonal relationships, and leisure time. It is the most common and severe form of psychotic illness with a prevalence estimated at about 1% (1).

Symptoms of schizophrenia usually develop between ages 16 to 30 years and persist through the patient's lifetime. Although the onset of illness is often gradual and insidious, all patients experience periods in which contact with external reality is grossly impaired (*active phase*). After the active phase, most patients continue to show signs of the illness (but at less than psychotic intensity) in a *residual phase*. Many patients show a pattern of progressive deterioration over time, with multiple episodes of active illness followed by accumulating residual symptoms.

Although a patient with schizophrenia may present in any phase of the illness, psychotic symptoms are a common presentation to the emergency department (ED). Worsening of their psychosis may be from a situational stress, an underlying medical condition, or nonadherence to their medication. They may also present with suicidal behavior, violence, or an adverse reaction to their

neuroleptics. As a general rule, any psychiatric symptom may be seen in the active phase of schizophrenia. However, in order for an episode to meet criteria for an active phase of schizophrenia, one of the "positive symptoms" of schizophrenia (delusions, hallucinations, disorganized speech, or disorganized behavior) must be present. Often, different positive symptoms co-occur during the active phase of schizophrenia.

Delusions are false beliefs, based on incorrect inference about external reality, that are firmly sustained despite what constitutes incontrovertible and obvious proof or evidence to the contrary. Common forms of delusions include persecutory, paranoid, grandiose, and somatic. Bizarre delusions involve beliefs that are patently false and totally implausible and nonsensical. Bizarre delusions are very frequent in schizophrenia and have increased diagnostic discrimination in comparison with nonbizarre delusions.

Hallucinations are perceptual experiences that have a compelling sense of reality, like true perceptions, but without external stimulation of the sensory organ. Hallucinations may occur in any sensory modality with auditory hallucinations being the most common. Hallucinations may be fleeting, recurrent, or continuous for years, and content varies from indistinct muttering to elaborate conversations involving several parties. Voices may be familiar or unfamiliar. Commonly the language is coarse, hostile, insulting, belittling, or derogatory, but it may also be comforting, praising, instructing, or neutral.

Grossly disorganized behavior encompasses a wide range of abnormalities such as prolonged childlike silliness, severe agitation, inability to satisfactorily complete normal activities of daily living, displays of affect markedly inappropriate to circumstances, intense verbal or physical aggressiveness that is unpredictable and unprovoked, and serious loss of normal social inhibitions, and other actions that seem so odd or unusual as to suggest that the individual is grossly out of contact with external reality. *Disorganized thoughts* include derailment, blocking, circumstantiality, tangentiality, neologisms, over inclusive, and concrete thinking.

Catatonia is a syndrome of abnormal motor control and responsiveness in patients who are otherwise alert and conscious (in fact, often these patients are hyperalert). Catatonia is often associated with schizophrenia, but it can also be seen in a wide variety of other psychiatric and medical conditions. Common symptoms of catatonia include *catalepsy* or *stupor, posturing, waxy flexibility,* and *mutism.* However, catatonia more rarely can present as *catatonic excitement* (a very dangerous state of extreme and constant agitation, hyperactivity, and purposeless motion) or *malignant catatonia* (an acute onset of fever, excitement, autonomic instability, and delirium).

By contrast, *negative symptoms* are those that suggest a loss or complete cessation of some normal mental function. *Affective flattening* or *blunting* is a marked reduction or absence of external signs of emotion. It includes generalized lack of responsiveness, immobile and unresponsive facial expression, decreased spontaneous movements, paucity of expressive gestures, poor eye contact, and lack of vocal inflection. *Alogia* is a reduction in quantity of thought, reflected in decreased fluency and productivity of speech. It includes *poverty of speech,* and *poverty of content of speech. Avolition* (apathy) is a reduction or loss of ability to initiate and persist in goal-directed activities, such as poor grooming, impersistence at work or school, and physical anergia (2).

Bipolar Disorder

Bipolar disorder (previously known as *manic depressive disorder*) is a mood disorder whose major feature is changes of mood from periods of mania to depression. The prevalence of bipolar disorder is 1% and, unlike unipolar depression, men and women are equally affected.

A manic episode is defined as a distinct period of elevated, expansive, or irritable mood that lasts for at least 1 week and causes marked impairment in functioning. The patient typically has an increased energy level, pressured speech, and a decreased need for sleep. The patient may also have racing thoughts, distractibility, and

flight of ideas. Patients may also get involved in activities with high potential for unpleasant consequences; for example, such as frequently spending money recklessly, becoming involved in high-risk sexual activity, and engaging in risk-taking behavior.

Delusions or hallucinations may be present, making it difficult to distinguish from schizophrenia. Grandiose delusions are frequently seen in mania and include having special powers or being a powerful figure. Manic patients are often impulsive, show poor judgment, and can have a great deal of disruption in their personal life. They can also cause a great deal of stress to their family, who are often the ones who refer the patient for emergency evaluation (3).

DIFFERENTIAL DIAGNOSIS

Patients presenting with psychotic behavior have a broad differential diagnosis. It may be a manifestation of schizophrenia, delirium or dementia, an underlying medical disorder, substance abuse, major depression, mania, or a delusional disorder. Transient hallucinations may occur in nonpsychotic mental disorders (acute bereavement) and are not considered psychopathologic.

The medical conditions that can cause manic or psychotic symptoms include disorders of the central nervous system (seizures, tumors, multiple sclerosis), metabolic (hyperthyroidism, hypoglycemia), infectious (encephalitis, pneumonia, uremia), and systemic (collagen vascular disease, lupus) diseases. Also, the effects of many substances (steroids, cocaine, alcohol) and medications (benzodiazepines), both in intoxication and withdrawal, can mimic these conditions (4).

ED EVALUATION

The role of the ED assessment in patients presenting with psychotic or manic behavior is threefold. First, and most importantly, is to recognize and treat any life-threatening medical conditions that may be causing or exacerbating the psychiatric complaints. Second is to rapidly stabilize the patient’s psychotic behavior and ensure safety

to the patient and providers. And lastly, often in consultation with a mental health professional, is to determine the appropriate disposition. The extent of the medical examination and evaluation depends on the patient's history and circumstances. New-onset psychosis in a previously normally functioning person strongly suggests a medical condition (particularly if the person is elderly). In cases wherein the patient has a long history of mental illness, including numerous hospitalizations and previous or current treatment, the cause of psychotic presentation may well represent worsening or recurrence of symptoms associated with the patient's ongoing psychiatric condition. Yet, psychosis may also be the effect of a new or worsening medical condition superimposed on the underlying mental illness (5).

The initial evaluation includes review of prehospital information gathered by police and emergency medical services (EMS). The physician encounter should consist of clear, simple, direct questions about the patient's chief complaint or reason for being in the ED in a tone that is understanding, calm, and nonjudgmental. The patient's speech and behavior should be observed for signs of disorganization, delusions, or hallucinations. Questioning about the onset of illness, psychiatric hospitalizations and other psychiatric care, and medical history are essential. Although patients may be forthright about the circumstances that led to an ED visit, much information can be gleaned from review of the medical record and collateral information provided by family and/or care providers. The mental status exam should include an assessment of general appearance, level of consciousness, mood, spontaneous speech, and orientation to time and place. All patients should have a complete set of vital signs. Abnormal vital signs should be addressed (particularly fever) and not prematurely be attributed to anxiety or agitation. The physical exam should be driven by the chief complaint, patient's mental status, psychiatric history, concurrent conditions, and age. Lastly, the physician should highlight the plan for subsequent management, for example, telling the patient that a mental health professional will be called in to help with additional

evaluation. Answers to the patient's questions should be clear, concise, and straightforward (6).

ED MANAGEMENT

Managing the undifferentiated agitated or psychotic patient remains complex and challenging especially if the patient is disruptive, argumentative, or refusing care. Not only must the ED physician attempt to deescalate the situation but also quickly ascertain whether the care providers, other patients, and the patient are safe from potential harm.

The initial step in treating an acutely psychotic patient is to make the patient aware of your concern about their behavior, offer assistance to help reduce their agitation, and acknowledge that they are safe. Patients with escalating aggression or agitation or potential for violence may require rapid tranquilization and physical restraint. This should be done rapidly, nonpunitively, and with appropriate well-trained staff (7).

Droperidol (Inapsine) and haloperidol (Haldol) are particularly effective when emergent sedation is needed for the safety of the patient and healthcare providers and are often used in conjunction with short-acting benzodiazepines. However, droperidol and haloperidol are not recommended (FDA Black Box warning) in patients suspected or known to have cardiac dysrhythmias or QT prolongation. Case reports have occurred in patients receiving droperidol at or below recommended doses, with no known risk factors for QT prolongation and some cases have been fatal. In September 2007, the FDA released a warning that torsades de pointes and QT prolongation might occur in patients receiving haloperidol, particularly when the drug is administered intravenously or at doses higher than recommended. These warnings, however, do not preclude their use, yet it is prudent to exercise caution when using them in patients who may have conditions that put them at risk for QT prolongation.

More recently, newer agents known as second-generation antipsychotics—risperidone, quetiapine, paliperidone, ziprasidone,

lurasidone, iloperidone, olanzapine, and aripiprazole—with less motor side effects (dystonia, akathisia or restlessness, parkinsonism, and neuroleptic malignant syndrome) have been introduced for treatment. The list of approved drugs for the treatment of bipolar disorder and schizophrenia continues to grow rapidly. Despite the initial enthusiasm that these agents would not only improve the positive psychotic symptoms, but also the negative and cognitive aspects of the illness, the efficacy toward negative and cognitive symptoms of the illness have not been borne out to date. Additionally, the second-generation antipsychotics, to different degrees, induce a high incidence of metabolic side effects (weight gain, hyperglycemia, diabetes, elevated triglycerides, and cholesterol) (8). However, second-generation antipsychotics offer calming effects with a far lower incidence of the acute dystonia or sedation seen with conventional antipsychotic agents. For patients with known schizophrenia or bipolar disorder presenting with psychotic symptoms in the ED, these agents are often first-line treatment (9). Oral doses should be offered first, and several agents are available in dissolvable forms. However, dissolvable tablets do not have a faster onset of action compared with their conventional oral dosage forms and possess the same side-effect profile. Antipsychotics should be avoided in elderly patients with dementia as much as possible. The FDA has given a Black Box warning for all antipsychotics for the treatment of elderly patients with dementia-related psychosis as these patients have a higher mortality rates as compared with placebo.

Sometimes a patient's behavior is extreme enough that seclusion or physical restraint is necessary to assure the safety of the patient and others. At all times, the least restrictive method should be used, and the patient should be closely monitored and reassessed. Physicians should be familiar with their facilities' current protocols and the laws regarding these measures.

CRITICAL INTERVENTIONS

- Administer chemical restraints with or without physical restraints to the agitated patient before the patient becomes violent.
- Patients requiring physical restraints must also receive anxiolytics and/or antipsychotics.

DISPOSITION

The acutely psychotic or manic patient needs evaluation by a mental health professional and, probably, hospitalization if the potential for violence or self-harm is suspected. The psychotic patient who expresses suicidal or self-harming thoughts or who has attempted suicide is at risk because he or she can exhibit unpredictable behavior in the immediate future.

New psychiatric symptoms (not caused by a medical condition) or worsening symptoms (suggesting some kind of crisis or management failure) should ideally be managed in the ED in consultation with a psychiatrist. Patients unable to care for self due to severe psychosis, chaotic living environment, poor judgment, confusion, or extreme impulsivity require mental health consultation and may need to be transferred to a facility that can accommodate observation and reassessment over a prolonged period of time. Patients with chronic stable psychiatric illness that appears to be under good control can be referred for outpatient management as circumstances dictate, but consultation with a mental health professional or a discussion with the patient's psychiatrist may facilitate evaluation and help ensure adequate follow-up (10).

Common Pitfalls

- Missing a life-threatening medical condition that presents primarily with abnormalities of thought and behavior.
- Neglecting to consider patients' risk of harm to themselves or others, owing to suicidal or homicidal ideation, impulsivity, or poor judgment.
- Attributing physical complaints to somatization without sufficient evaluation to rule out a concurrent emergent medical condition.

CHAPTER 167 The Agitated or Violent Patient

Katherine Bakes and Vincent J. Markovchick

One of the most common and dramatic patient presentations in the emergency department (ED) is the out-of-control, agitated, and violent patient. Screaming and combative behavior immediately get the attention of staff, patients, and visitors. Violence is a substantial ED problem, with one study reporting 75% of attending physicians experiencing verbal threats, 28% a physical assault, 12% confrontation outside of the ED, and 4% victimization by stalking (1). An Emergency Nurses Association (ENA) survey found 86% of emergency nurses reported having been a victim of job-related violence (2). Nurses are in fact more likely to experience violent events than physicians, with more associated acute stress and commensurate decrease in productivity (3).

Times of ED crowding are particularly high risk for violent events, with one study showing a fourfold odds of experiencing patient care–related violence increased over baseline (4). With two-thirds of US metropolitan EDs experiencing crowding, it is crucial to develop evidence-based institutional protocols to address times of heightened violence risk, particularly at a time when the Affordable Care Act may lead to increased ED volumes. Formal security plans, which include environmental modifications, employee education and training, use of security and law enforcement, surveillance, and the discovery and handling of concealed weapons, have demonstrated decreased employee assault rates.

Treatment of the violent or agitated patient often begins in the field by emergency medical technicians (EMTs) and law enforcement. If possible, advanced notification via communications with field personnel should be provided to the ED so as to mobilize the resources and the beds for management of such patients. This will obviate the situation wherein a patient is held in a public area such as a hallway for a prolonged period of time while the staff scrambles to free up a bed in an appropriate treatment room.

When necessary for patient care or provider safety, chemical sedation or physical restraint can commence in the field, necessitating the appropriate prehospital protocols. EMTs should contact the base station to discuss appropriate treatment of such patients and to give advance notification of patient arrival. In many instances, it is not possible to obtain a coherent history from the patient. Careful questioning of EMTs, family members, bystanders, friends, or anyone else who has observed the evolution of this patient's behavior should be undertaken. Members of appropriate personnel, including security, should be mobilized to safely transport and, when necessary, physically restrain such patients. The situation must be brought under control expeditiously to ensure the safety of staff and the patient, and to prevent secondary effects of severe agitation such as hyperthermia, metabolic acidosis, and rhabdomyolysis.

DIFFERENTIAL DIAGNOSIS

The first role of the emergency physician is to rapidly identify reversible causes of acute organic brain syndromes that, if not treated, may cause morbidity and potential mortality. Examples of these are hypoglycemic reactions, hypoxia, thyroid storm, bath salts abuse, severe amphetamine or cocaine toxicity, hyperthermia, anticholinergic toxicity, and alcohol intoxication or withdrawal. In addition, the ultimate role of the emergency physician is to differentiate organic from functional disorders. (See Chapter 152 for a detailed description of the mental status examination and the differentiation of organic from functional disease state.)

Evaluating for quickly reversible causes of agitation should include a point-of-care blood glucose test (hypoglycemia), oxygen saturation measurement (hypoxia), and a physical examination for the presence of possible toxidromes. Life-threatening sympathomimetic agitated states (i.e., cocaine and methamphetamine intoxication) may be identified by the presence of one or more of the following: significant tachycardia, hypertension, hyperthermia, extreme violent muscular activity, and dilated pupils. Violent postictal states may be identified by a history of a seizure and secondary signs on physical examination of major motor seizures (i.e., tongue lacerations and incontinence). When feasible, a mini-mental status examination should be performed as well as a complete neurologic examination.

If any focal neurologic deficits are identified, the differential diagnosis should be expanded to include central nervous system pathology such as brain tumors, seizures, ischemic stroke, or intracranial hemorrhage. Specific toxidromes should be identified (i.e., hyperthermic, sympathomimetic, anticholinergic, and cholinergic presentations), as each requires a specific therapy. Features of delirium, new violent or psychotic behavior (particularly in patients older than 40 years of age), abnormal autonomic signs, visual hallucinations, or an acute time course should raise a concern that the cause of the patient's agitation may be organic in nature.

Alcohol intoxication is a frequent ED presentation and has been linked to aggression. The association is attributed to cognitive and emotional difficulties: decreased tolerance for frustration, diminished capacity to perceive and process multiple cues at once, increased response to strong situational stimuli, limitations in problem-solving despite an exaggerated sense of power, and a diminished appreciation for consequences with associated increased risk-taking behaviors.

"K2" and "Spice" are examples of a relatively new class of designer cannabinoids. Easily available on the Internet and some convenience stores, these drugs are sometimes referred to as "legal highs" due to their ability to evade standard drug screens (5). Numerous formulations of designer cannabinoids are available, from

powders and liquids, to smoking mixtures, with case reports describing a myriad of effects, from nausea to psychomotor agitation, diaphoresis, and palpitations. Other reports have included sedation, hot flushes, burning eyes, xerostomia, mydriasis, tremors, palpitations, and tachycardia (6).

Excited delirium syndrome (ExDS) was first described in forensic literature as delirium with severe agitation that, if untreated, can lead to death. In a 2009 consensus white paper, the American College of Emergency Physicians (ACEP) recognized ExDS as "a unique syndrome which may be identified by the presence of a distinctive group of clinical and behavioral characteristics that can be recognized in the pre-mortem state" (7). Although an imprecise syndrome, clinical features include tolerance to significant pain, rapid breathing, sweating, severe agitation, elevated temperature, delirium, noncompliance or poor awareness to direction from police or medical personnel, lack of fatiguing, "superhuman" strength, and inappropriate clothing for the current environment. Because ExDS deaths have occurred with minimal restraint, early chemical sedation is recommended.

ED EVALUATION AND MANAGEMENT

Staff safety and expeditious control of the violent or agitated patient should not overshadow the need to consider an organic etiology for violent behavior. Easily diagnosed and reversible etiologies for agitation should be quickly excluded or treated. A thorough physical examination, including a reliable temperature and pulse oximetry, is mandatory and may require chemical sedation to obtain. Fever with agitation or violence, without a clear explanation, necessitates a sepsis workup. If the workup fails to identify an etiology and the patient has an organic brain syndrome, a head computed tomography scan and lumbar puncture should be considered to exclude intracranial pathology. Hypoxia must be quickly excluded as a cause of aggressive behavior and treated appropriately. Likewise, hypoglycemia must be diagnosed rapidly, either at the time of IV placement or with a finger stick after physical restraints

are instituted. A toxidrome-focused examination should be performed, which includes vital signs, pupillary and skin evaluation, lung and bowel sounds, and neurologic assessment including mental status. If the history and physical examination do not lead to a clear cause for agitation, laboratory studies such as a urine toxicology screen and serum electrolytes can be considered.

Although control of the violent patient is paramount in ensuring the safety of the ED staff and patients, the need for chemical sedation or restraints may be avoided by applying some basic principles when evaluating the volatile individual. Once in the ED, some simple preventative protocols for decreasing the risk of violence include having patients change into hospital gowns to allow for further searches and a complete physical evaluation. Providers should utilize preventative communication measures for escalating violent behavior such as maintaining an adequate distance from the agitated patient, calmly explaining intentions and the plan to the patient and ED staff, engaging in nonthreatening verbal and nonverbal communication, acknowledging the agitated patient's concerns, and having an exit strategy that includes how to call for help (8).

Features suggesting an organic etiology include a rapid onset, no prior history of psychiatric disease (especially if >40 years of age), visual–olfactory–tactile hallucinations, abnormal vital signs, cognitive deficits, slurred speech, confusion, evidence of substance abuse, disorientation, and a history or physical evidence of trauma.

One staff educational crisis intervention (SECI) on ED violent behaviors significantly reduced patient violence from 17% to 7%. The SECI program included education for physicians, nurses, and security staff that focused on the following: early recognition of potential violent behaviors, team protocols, and awareness of guidelines; regular staff dialog around violence and restraint; medical presence during all security interventions for restraint; and debriefing after each intervention (9). Although no longer required by the Joint Commission, debriefings are recommended, with many institutions utilizing the Crisis Prevention Institute's (CPI) train the trainer model of crisis management and de-escalation.

Pharmacologic Management

When de-escalation techniques fail, chemical sedation can and should be used to prevent harm to patients and staff members. The most common drugs used for this purpose include the neuroleptics haloperidol and droperidol, as well as the benzodiazepines midazolam, diazepam, and lorazepam. Haloperidol should be dosed 5 to 10 mg intramuscular (IM) every 10 to 30 minutes. Peak serum levels occur approximately 30 minutes after IM and 3 to 6 hours after oral administration. Unlike the phenothiazines such as thioridazine, haloperidol does not cause respiratory depression, has negligible anticholinergic side effects, and rarely causes hypotension. A 2012 Cochrane review on the use of haloperidol for psychosis-induced agitation or aggression found that haloperidol should not be given alone, but rather in combination with the anticholinergic-antihistamine promethazine (up to 50 mg), which enhances haloperidol's tranquilizing effects while minimizing undesirable side effects such as acute dystonia (10). The traditional combination of haloperidol plus a benzodiazepine was never a highly rated alternative (11).

Owing to the high potency of haloperidol, extrapyramidal side effects (dystonia, torticollis, opisthotonos, or oculogyric crises) are common and not dose-related, occurring in 20% of people in the first 24 hours. Akathisia, a feeling of uneasy restlessness, has been reported to occur in up to 75% of people receiving 5 mg of haloperidol. Fortunately, these side effects are easily treated in minutes with diphenhydramine 25 to 50 mg IM or IV or benztropine 2 mg IM or IV. Prophylactic treatment should be considered in patients with a history of or a fear of developing extrapyramidal side effects. Because the onset of side effects can be delayed on the order of hours, the patient can be prescribed oral benztropine 2 mg or diphenhydramine 25 mg at discharge and instructed to take them if symptoms develop. Although more common with the low-potency antipsychotics, haloperidol also has the theoretical potential to lower the seizure threshold and thus should be avoided with

patients who are postictal, prone to seizures, or experiencing amphetamine or cocaine toxicity.

In 2007, the FDA has published a “Black Box” warning for the IV use of haloperidol owing to a dose-dependent IV risk of prolongation to the QT interval. These warnings are often based on rare events through voluntary reporting, which can be biased or incomplete and often lack proof of causality. Ironically, many common ED medications can prolong the QT interval, including antiarrhythmics (e.g., amiodarone, procainamide, adenosine), most antiemetics (e.g., ondansetron), antimicrobials (e.g., erythromycin, azithromycin, moxifloxacin, levofloxacin, fluconazole), antipsychotics (e.g., haloperidol, quetiapine), antihistamines (e.g., diphenhydramine, hydroxyzine, loratadine), antihypertensives (e.g., nicardipine), and tricyclic antidepressants (12).

Based on case reports of potentially fatal cardiac events, the FDA has revised the label for haloperidol, warning that the QT prolongation and risk of torsade de pointes were increased with IV administration, particularly when given to patients on other QT-prolonging medications or at greater than recommended doses; the FDA went on to recommend continuous ECG monitoring with the administration of IV haloperiodol (13). Since the warning, investigators have shown that a total cumulative dose of IV haloperidol of <2 mg can safely be administered without ongoing electrocardiographic monitoring in patients without concomitant risk factors (underlying heart conditions, electrolyte imbalances such as hypokalemia and hypomagnesemia), concomitant proarrhythmic drug use, and mechanical ventilation (13).

Droperidol (2.5 to 5 mg IM or IV), another antipsychotic, has a shorter half-life than haloperidol. Droperidol’s antiemetic effect is advantageous for patients restrained supine and at risk for vomiting and aspiration. As with haloperidol, droperidol has demonstrated a risk of increasing QT intervals, and thus also carries an FDA Black Box warning. Droperidol’s Black Box warning was given after reports of adverse events were submitted through MedWatch from 1997 to 2001 and published in two studies reporting prolongation of the QT intervals (12). In a 2003 review of the literature surrounding

the FDA position as well as local experience of approximately 12,000 patients over a decade, Shale et al. (14) concluded that the evidence does not support discontinuation of droperidol for control of the violent patient. They noted that the evidence for the FDA warning was based on 100 adverse cardiovascular events and either 18 or 25 deaths (depending on conflicting reports) (14).

Unfortunately, all neuroleptics have the potential of causing dose-dependent prolongation of the QT interval and precipitation of torsade de pointes by blockade of cardiac potassium channels. Thioridazine was given an FDA Black Box warning in 2000 owing to multiple reports of sudden unexplained cardiac deaths. Droperidol has also carried an FDA Black Box warning since 2001, owing to an apparent association with QT prolongation, and its use has significantly decreased, presumably because of fear of adverse outcomes (15,16). However, as with all medications, its use should be based on a risk–benefit analysis.

The three benzodiazepines often used for sedation are midazolam, lorazepam, and diazepam. Although diazepam is often preferred owing to its low cost, lorazepam and midazolam have the advantage of superior IM absorption and bioavailability. Lorazepam is preferred in patients with cirrhosis or alcohol dependence, as its metabolism is maintained in the setting of liver disease. The side effects of these medications are mainly sedation and respiratory depression. Large doses of benzodiazepines, as may be necessary for acute amphetamine or cocaine toxicity, may be given only in a closely monitored environment wherein active airway control may be instituted if respiratory depression ensues.

A double-blind randomized clinical study of 180 acutely agitated ED patients compared 5 mg of IV midazolam with droperidol every 5 minutes. Midazolam was found to produce more sedation than droperidol at 5 minutes but equivalent sedation at 10 minutes. The midazolam group had statistically more adverse events related to airway management, with three patients requiring transient assisted ventilation and one requiring endotracheal intubation. Of note, the QT_c at 30 minutes did not differ between the groups, and there were

no adverse events related to QT prolongation (17). The TREC (rapid tranquillization clinical trial) collaborative group conducted a randomized controlled trial of 301 patients with acute agitation and compared midazolam 15 mg IM with haloperidol 5 mg or 10 mg IM plus promethazine 50 mg IM. Midazolam was statistically more effective than haloperidol plus promethazine at producing sedation at 20 and 40 minutes after injection. Twice as many patients in the midazolam group were asleep at 20 minutes as were in the haloperidol group. Two severe adverse events were noted: one patient with epilepsy developed a seizure after haloperidol plus promethazine injection, and one patient in the midazolam group developed respiratory depression and cyanosis requiring reversal with flumazenil (18). Multiple investigators have evaluated the combination of a benzodiazepine with a neuroleptic for the control of acute agitation. However, the recent Cochrane review on haloperidol found no benefit in combining haloperidol with lorazepam for acute control of the agitated patient; evidence does not support regular use of these combinations (10).

The newer atypical antipsychotics are also being investigated for the use in acute behavioral control. These agents, which include risperidone, olanzapine, and ziprasidone, may be more expensive, but often have a more favorable side-effect profile. Experience with these medications in the emergency setting is limited, however (16). These medications also have the propensity to cause QT prolongation, although none currently carry an FDA Black Box warning.

When an organic etiology of agitation is suspected or if there is no clear psychiatric diagnosis, providers should use IM haloperidol or IM benzodiazepine alone. For primary psychiatric disorders such as schizophrenia, psychotic depression, and personality disorders, IM olanzapine or ziprasidone are preferred over IM haloperidol. In cases of mania, risperidone, alone or with a benzodiazepine, is recommended over haloperidol (11).

IM ketamine (5 mg/kg) or IV ketamine (1 mg/kg) has been used for some time outside of the United States for sedation of the agitated patient. A small retrospective study of 11 trauma patients

in the prehospital setting reported its effectiveness, but there are concerns with potential side effects of increased oral secretions, vomiting, laryngospasm, hypertension, and emergence phenomena. However, no drug used in this setting is without risks, and ketamine may prove a useful addition to the armamentarium of the emergency physician who needs immediate control over an aggressive or dangerous patient. A study of 13 patients receiving prehospital ketamine found that 3 patients developed hypoxia (2 requiring intubation) and 10 had emergence reactions which were successfully treated with small doses of benzodiazepines (19).

Although further evidence is needed, ketamine has shown to be successful in small samples of patients with ExDS (20). The ACEP consensus group recommends immediate control of ExDS, endorsing early use of benzodiazepines, ketamine, or intranasal midazolam for speedy chemical control.

Physical Restraints

Unfortunately, many patients prove too agitated for the aforementioned approach, and necessitate physical restraints. ED staff should avoid hogties or hobble restraints, whereby the patient's hands and feet are tied together behind the back. This method of physical restraint has occasioned multiple reports of sudden death, particularly when the patient was kept in the prone position and in the setting of intoxicants. One study found that compared with the supine position, hobble restraints significantly impacted respiratory function and were associated with decreased forced vital capacity, forced expiratory volume, and maximal ventilation.

When necessary, four-point soft leather restraints should be utilized. At least five staff members should restrain the patient, one for each limb and a fifth to stand at the head of the bed to calm and to explain the process to the patient. To avoid undermining a therapeutic relationship with the patient, the physician should not be a member of this team. Restraints should be secured firmly, yet loosely enough to allow a finger to move between the restraint and the extremity. All patients should be assumed to be at risk of

aspiration and therefore should be restrained on their side or with the head of the bed slightly elevated. Restraint of an upper limb in hyperabduction and extension for a prolonged period of time may cause peripheral nerve injury, so it should be repositioned at the patient's side as soon as adequate control of the patient is attained.

The Centers for Medicare and Medicaid Services (CMS), which works with the Joint Commission, has put forth guidelines on the use of seclusion or restraint (see below). Although restraint-related complications are infrequent, to maintain patient rights and avoid the liability associated with placing a patient in restraints, a hospital protocol should be established. It should include documentation of the following: necessity of restraints, alternative measures attempted, and orders for the continuation of restraints and decided end-points for discontinuation of restraints. The Joint Commission requires that a patient be assessed every 15 minutes after placement of restraints for signs of injury associated with the application of restraint or seclusion; nutrition and hydration; circulation and range of motion in the extremities; vital signs; hygiene and elimination; physical and psychological status and comfort; and readiness for discontinuation of restraint or seclusion (21). The use of restraints can be minimized; the most successful institutional protocols for reducing the need for physical restraint include leadership involvement, facility culture change, the learning of concrete de-escalation skills, and the use of data to drive system change (11,22).

Federal directions on the use and standards for seclusion or restraint include the following:

- Physician or other independent licensed practitioner must see and evaluate patient within 1 hour of initiating intervention.
- Use of seclusion or restraint only when clinically justified and after consideration of alternative treatment options.
- Time-limited orders: 4 hours for adults; 2 hours for adolescents; 1 hour for children (<9 years old), with renewal after 24 hours requiring a physician or licensed independent practitioner to see and assess the patient.
- Continuous in-person patient monitoring and periodic re-evaluation with the intent to discontinue intervention at the

earliest possible time; face-to-face re-evaluation before each renewal of initial time-limited orders.

- Notification of clinical leadership (i.e., medical director) after 12 hours of continuous seclusion or restraint and every 24 hours thereafter.
- With patient-informed consent, prompt family notification when seclusion or restraint is initiated.
- Deaths must be reported to the CMS (12).

Unfortunately, often not discussed is the cost to the healthcare provider caring for the traumatized, agitated, or violent patient. Secondary traumatic stress (STS) or compassion fatigue (CF) are common culprits of burnout in emergency medicine. A study of emergency nurses found that 54% reported irritability, 52% avoidance of patients, and 46% intrusive thoughts about patients; in all, 33% met all criteria for STS (23). STS disorders typically go unrecognized by affected personnel, despite chronic and critical incident stressor putting providers at risk for posttraumatic stress reactions and subsequent substance abuse (24). Emergency providers should be monitored for appropriate self-care, cognitive and emotional changes (e.g., difficulties with safety, trust, control, or intimacy), and healthy work–life balances (25). Involvement in stress management activities can prevent or minimize STS symptomatology (23).

CRITICAL INTERVENTIONS

- Diagnose and treat reversible causes of agitation, such as hypoxia and hypoglycemia.
- Approach the volatile patient in a safe environment, utilizing de-escalation techniques.
- Use a documented hospital-based protocol after instituting physical restraints that includes justification for its use and frequent reassessment of the patient's condition.
- Obtain pharmacologic control of the violent medical patient using an atypical antipsychotic, with or without a benzodiazepine.

- Obtain pharmacologic control of the violent psychiatric patient using haloperidol and/or a benzodiazepine.

DISPOSITION

Once the patient is under control and an organic etiology has been excluded, disposition will depend on the patient's course in the department. The patient might require psychiatric evaluation for suicidal or homicidal ideation or for being gravely disabled. Alternatively, the patient may be discharged once the acute violent or agitated behavior subsides. This usually requires a short observation period until an intoxicant is metabolized. Finally, if the patient has been physically violent toward staff, he or she may be arrested and discharged to the appropriate authorities.

Common Pitfalls

- Failure to undress the patient and search for weapons.
- Failure to take steps to minimize the risk of aspiration and peripheral nerve injury in a restrained patient.
- Failure to provide adequate doses of sedative agents.

CHAPTER 168

Factitious Illness, Malingering, and Conversion Disorder

Jeffrey S. Dubin and Mark Smith

Factitious disorder, malingering, and conversion disorder constitute a spectrum of medical conditions in which the patient's symptoms are false, pretended, or grossly exaggerated. The patient's symptoms may be voluntary (malingering and factitious disorder) or may be an involuntary expression of an underlying psychological conflict (conversion disorder) (1). Distinguishing the physiologic conditions from the functional while addressing the patient's psychologic issues is a test of the emergency physician's diagnostic acumen and therapeutic skill.

FACTITIOUS DISORDER

CLINICAL PRESENTATION

The syndrome of factitious disorder with physical symptoms is better known as Munchausen syndrome, named by Asher (2) after novelist Rudolph Raspe's character, Baron Munchausen, who enjoyed a series of fabricated adventures. Munchausen patients are impostors who invent bizarre and often fantastic stories and accept painful and potentially dangerous procedures (e.g., cardiac catheterization, exploratory laparotomy) to reach their presumed goal: to become a patient and assume the "sick role" (1). There is no

other secondary gain, thus distinguishing the Munchausen patient from the malingerer.

Munchausen patients typically present to the emergency department in a dramatic fashion, with a constellation of physical symptoms, plausibly suggesting the presence of substantial pathologic illness that is not present. Examples of Munchausen practices:

- Applying mydriatics to stimulate anisocoria (3)
- Misusing an insulin pump to induce hypoglycemia (4)
- Creating skin lesions or placing foreign bodies in skin (5)
- Overdosing with caffeine to induce tachyarrythmia (6)
- Feigning respiratory distress that results in intubation (7)

Munchausen patients are typically young or middle-aged men (although the age range spans the pediatric to the geriatric) and often report a medical history of previous hospitalizations and operations, in many cases performed in other cities. They are knowledgeable about hospital routines and may have worked in the medical field but are often vague or inconsistent about their own medical details. Munchausen patients are clever, realistic, and facile in their simulation of clinical reality, but the extent and severity of symptoms are often out of proportion to physical findings and demeanor, and may seem almost too classic. The Internet has not only made it easy for Munchausen patients to find descriptions of disease symptoms to mimic, but has enabled a new outlet for the medical imposter. Munchausen by Internet has been described when persons without disease join Internet support groups and pose as having true illness and disrupt these online communities (8).

Munchausen patients have been characterized as hostile, dependent persons with poor impulse control and a history of self-destructive behavior. They tend to be socially isolated, rarely are accompanied to the emergency department by friends or family and, once admitted to the hospital, usually have no visitors. When confronted, they usually become hostile and querulous, deny the allegation of factitious disorder, and sign out of the hospital against medical advice.

When parents falsify illness in their children, the disorder is termed *factitious disorder by proxy* (FDBP). FDBP describes abuse in which the perpetrator (most often the mother) is motivated by the desire to assume the sick role by proxy or to seek attention from the hospital staff (1). Whenever this diagnosis is considered, it is important to define the specific abuse to the child. FDBP refers to the context of the abuse and the disorder of the parent. FDBP is child abuse and should be treated as such (9). Examples of FDBP are as follows:

- Infant apnea, cyanosis, seizures from smothering (9)
- Severe diarrhea and hypernatremia in infant (10)
- Factitious hypoglycemia in children (11) and elders (12)
- Self-induced premature labor and resultant neonatal injury (13)

DIFFERENTIAL DIAGNOSIS

Munchausen syndrome must be distinguished both from organic disease and malingering and from three conditions in which the production of nonorganically based symptoms is not voluntary: conversion disorder, somatization disorder, and hypochondriasis.

In the absence of explicit evidence to the contrary, the clinician should presume that there is an organic basis for the patient's complaints. When the patient fits the pattern of presentation for Munchausen syndrome, however, evidence should be sought to confirm or disprove that suspicion. In contrast to the Munchausen patient, the *malingerer* has a clearly understandable external incentive and goal other than wanting to be a patient. In the three somatoform disorders (conversion disorder, somatization disorder, and hypochondriasis), the patient's symptoms are involuntary. *Conversion disorder* is discussed in subsequent paragraphs. The patient with *somatization disorder* has a chronic history of multiple symptoms involving different organ systems in a fluctuating and recurrent pattern that is not adequately explained by a physical disorder. The *hypochondriac* patient presents with fear and concern about the presence of disease and, despite reassurance, misinterprets

normal bodily sensations and physical signs as pathologic conditions.

ED MANAGEMENT

Until a diagnosis of factitious disorder is confirmed, the patient should be treated as if an organically based disease is present. The usual diagnostic and therapeutic procedures should be followed. There are a myriad of symptoms and signs that patients with factitious disorder may feign. Kenedi et al. have compiled an extremely useful table of diagnostic tools clinicians should consider when evaluating suspected Munchausen patients (14).

If Munchausen syndrome is suspected but not confirmed, the physician may treat the patient in a modified manner (e.g., consider serial cardiac enzymes, no potentially harmful medications, and discharge home rather than admission for a suspected Munchausen patient with chest pain and normal ECG). When Munchausen syndrome is confirmed, the physician may elect to confront the patient in a supportive and nonthreatening manner, although the establishment of a therapeutic alliance between patient and physician is unlikely. There is no difference in outcomes of a confrontational versus nonconfrontational approach; most Munchausen patients will not participate in psychotherapy (15).

Patients who are labeled with Munchausen syndrome can still become organically ill. Procedures that have been performed because of their imposture may predispose them to real illness (e.g., a small-bowel obstruction may occur as a result of adhesions from a previous exploratory laparotomy for abdominal pain). Other patients may need medical treatment for self-induced physical ailments. The physician must not neglect to care for these patients because of their underlying psychopathologic condition.

An important caveat in the diagnosis of FDBP is that this is a very challenging diagnosis to make. If FDBP is suspected, consultation with a child abuse specialist is recommended prior to contacting child-protective services to help confirm these suspicions or avoid misdiagnosis in cases where no abuse exists (16).

DISPOSITION

If any doubt exists about the diagnosis of Munchausen syndrome and if the purported illness warrants hospitalization, the patient should be placed in observation for further evaluation. If the diagnosis of Munchausen syndrome is certain, however, the patient should be denied admission to the hospital for the presenting complaint. Psychiatric care is of little value and likely to be refused, if offered.

MALINGERING

CLINICAL PRESENTATION

Malingering is the voluntary and conscious presentation of false and exaggerated physical or psychological symptoms in pursuit of a recognizable goal. Such goals typically include avoiding work or other unpleasant obligations, obtaining shelter, obtaining controlled substances, or obtaining financial compensation through litigation. Malingerers may either exaggerate or invent symptoms.

In contrast to factitious disorder, in malingering the goal is clear and understandable, the behavior is conscious and situationally appropriate, and the symptoms abate once the goal is attained.

Malingerers present to the emergency department with a variety of demands or complaints. Some patients who complain of migraine headache or renal colic are seeking narcotic analgesics. Noncontrast helical computed tomography scan or sonography for nephrolithiasis is helpful, as the presence or absence of hydronephrosis is useful in distinguishing whether the possibly chronic stone is responsible for the degree of pain presented by the patient. Other individuals may present to the emergency department after missing several days or even weeks of work and request a retroactive “sick slip” because of a medical problem, the presence of which is difficult to document definitively. Patients who have been in minor motor vehicle accidents may present with exaggerated symptoms of cervical or lumbar strain in an effort to document damages and collect financial compensation.

Patients with underlying psychiatric disorders may feign exacerbations of mood and thought disorders so as to be hospitalized for secondary gain. These patients can be difficult to evaluate. Often they are admitted to the psychiatric service with a comorbid psychiatric diagnosis, with malingering strongly suspected.

DIFFERENTIAL DIAGNOSIS

Malingering is suggested if the patient over-dramatizes complaints, symptoms, or physical signs; overreacts during the physical examination; is uncooperative during the diagnostic evaluation; declines to appear when scheduled for diagnostic testing; or is reluctant to accept a favorable prognosis. The history, physical examination, and laboratory data may not support the severity of the patient's complaints, particularly those that lack objective correlates for diagnosis (e.g., migraine). During their evaluation, some patients may reveal their true objectives (e.g., a prescription for narcotic analgesics or a medical excuse from work).

Patients apparently suffering an acute neuromuscular syndrome may complain of symptoms that do not fit an anatomically consistent pattern or may exhibit weakness during testing that is belied by their ability to carry out other activities when they are not being examined. Patients complaining of low-back strain may demonstrate a disparity between the "straight leg-raise" test performed in a sitting versus supine position and, while in the supine position, the patient may not make an appropriate effort at raising the affected leg (detectable by placing a hand under the contralateral heel and feeling for the expected downward pressure associated with true effort).

If drug-seeking behavior is suspected, a review of past medical records or state narcotic database or other prescription database may be enlightening.

ED MANAGEMENT

Because the malingering patient may become defensive, angry, and hostile when confronted with the suspicion that the symptoms are false or exaggerated, the physician is often tempted to comply with the patient's demands rather than risk a confrontation. Furthermore, the diagnosis of malingering can rarely be made with complete certainty. Because each patient reacts to illness or injury differently, the degree of volition or willfulness that underlies the patient's exaggeration of symptoms is not always clear.

Perhaps a prudent way to deal with a suspected malingerer is to give the patient a minimal amount of gratification and to invoke general rules or established policies that prevent the physician from filling the patient's demands completely. It is worthwhile to record on the patient's chart suspicions or questions about the patient so that the next treating physician is aware of the concerns.

DISPOSITION

The usual criteria for admission to the hospital should apply, depending on the patient's complaint. If the physician is convinced that the patient is malingering, a firm stand should be taken against admission.

CONVERSION DISORDER

CLINICAL PRESENTATION

Patients with conversion disorder present with physical symptoms that are not under voluntary control and cannot be explained as a manifestation of a physical disorder or on the basis of a pathophysiologic mechanism. The physical symptoms are unconscious expressions of underlying psychological conflict. These symptoms are often immediately preceded by an acute psychological stress, and that precipitant should be sought. Conversion disorder was previously called *hysterical neurosis, conversion type.* Conversion symptoms have long been theorized to result from an autohypnosis after a traumatic event. Furthermore, adult victims of severe childhood abuse appear to be more prone to

developing conversion reactions as adults compared with their nonabused peers (17). Patients with conversion disorder often have other somatoform disorders (18).

The most typical conversion symptoms involve loss of neurologic function: blindness, aphonia, psychogenic seizures, paralysis, anesthesia, tunnel vision, gait abnormality, unresponsiveness, and amnesia (19). The conversion disorder symptom usually has a sudden onset. *La belle indifférence,* an attitude of relative unconcern despite the seriousness of the symptom, has historically been cited as a sign of conversion disorder. However, comprehensive review of the literature concluded that seeming unconcern on the part of the patient does not distinguish between conversion disorder and a stoic response to an organic disease (20). The diagnosis of conversion disorder depends on demonstrating that the patient's symptoms are not due to organically based malfunction. With most neurologic presentations of conversion disorder, this is not difficult, because the patient's deficits usually do not make neuroanatomic sense. The physician's knowledge of neuroanatomy is usually better than the patient's; moreover, the patient is not consciously trying to fool the physician. Nevertheless, these cases may sometimes mimic real disease patterns, including classic stroke presentations (21).

Typical "mistakes" made by the conversion disorder patient with neurologic symptoms include the following:

- Acute onset of sensory loss in a sharp stocking-glove pattern (although this may be mimicked by the peripheral neuropathies of diabetes or alcoholism)
- Complete paralysis and sensory loss of one leg, with preservation of deep-tendon reflexes and antigravity muscle activity
- Hemianesthesia without contralateral pain-temperature loss or with nonanatomic midline splits in vibratory sensation
- Complete loss of motor function on one side of the body, with inability to turn the head to the side of paralysis (indicating contralateral sternocleidomastoid muscle dysfunction)
- Psychogenic seizures: Features include presence of fluttering eyelids or closed eyelids, thrashing of extremities, pelvic

thrusts, and evidence of responsiveness to environmental stimuli during an apparent grand mal seizure. Typically absent are tongue biting, incontinence, physical injury, or postictal state (22)

- Inconsistencies in physical signs during unresponsiveness: Will not permit an upraised and suspended arm to strike the face when released but rather allows it to glide harmlessly over the face (note that substantial injury can occur to the nose and mouth if the arm does drop directly onto them). Vigorously resists manual eye opening by the physician (23)
- Inconsistencies in blindness: Ability to avoid injury and misstep when "blind" or with tunnel vision the visual field extending into space may be described as cylindrical rather than cone-shaped

DIFFERENTIAL DIAGNOSIS

Conversion disorder must be distinguished from organic illness, malingering, and Munchausen syndrome as well as from somatization disorder and hypochondriasis.

The tendency should be strongly resisted to diagnose conversion disorder in any patient with vague symptoms. Up to 30% of patients who have been given a diagnosis of conversion disorder at some time are eventually found to have organic disease that could explain these symptoms (24). Illnesses such as systemic lupus erythematosus, multiple sclerosis, and hyperthyroidism may present in the emergency department as subtle perturbations of physical functions; hypoglycemia can present in myriad different guises.

Patients with conversion disorder lack the characteristic features of the Munchausen patient: There is no tendency to submit to multiple procedures, and there is a lack of sophistication with respect to medical terminology. Unlike the malingering patient, there is no conscious fabrication of illness or disability.

ED MANAGEMENT

Patients with conversion disorder must be handled delicately, deftly, and with respect. These patients have usually experienced a recent or remote traumatic experience. It is unacceptable to confront the patient with an assertion or proof that the illness is faked or not real. The patient should be told that, although the symptoms are bothersome, they do not appear to be manifestations of a serious illness. Planting the suggestion that they will improve over the next several hours can sometimes relieve symptoms. Patients with aphonia can be told that they will be able to whisper; patients with paralysis can be told that they will begin to experience movement in their toes. Simultaneously, the physician can probe for underlying psychosocial conflicts that might have led to the appearance of the symptom.

CRITICAL INTERVENTIONS

- Treat patients with suspected but not confirmed Munchausen syndrome as if an organically based disease is present until the diagnosis is confirmed.
- Resist diagnosing conversion disorder in any patient with vague symptoms.
- Treat suspected malingering patients with a minimal amount of gratification and invoke general rules or established policies that prevent the provider from fulfilling the patient's demands completely.

DISPOSITION

The neurologic consultant may assist the physician in differentiating organic from nonorganic illness. If the diagnosis of conversion disorder is secure and the patient's symptoms persist and prevent the patient from carrying out the activities of ordinary living, a psychiatric consultant may assist in the process of symptom resolution in the emergency department.

Many patients with conversion disorder experience resolution of their physical symptoms during their emergency department stay, but some require admission to the hospital. If the diagnosis of

conversion disorder is uncertain and if the presenting symptom could signify dangerous illness, hospital admission is warranted. Even when the diagnosis of conversion disorder is clear, patients whose manifestations persist and who cannot manage on their own (e.g., psychogenic unresponsiveness or paralysis) require inpatient care.

Common Pitfalls

- Failing to appreciate that the patient has an unusual presentation of an organic illness.
- Permitting unpleasant aspects of the patient's personality to result in dismissal of the patient's problem as "psychogenic."
- Inadequately distinguishing among malingering, conversion disorder, and Munchausen syndrome.
- Classifying all patients with symptoms having no discernible anatomic cause as "crocks."
- Losing interest in caring for the patient once it has been determined that the patient's symptoms are not organically based.

CHAPTER 169 Bereavement and Grief Reactions

Kenneth V. Iserson

Death, especially when it is sudden and unexpected—as often happens in the emergency department (ED)—shocks and devastates patients' family and friends. For them, it is a sentinel, life-changing event, with every nuance burned into their memories. As Thomas Mann wrote, "A man dying is more the survivors' affair than his own" (1). Furthermore, such losses may deeply affect emergency medicine personnel, despite their almost constant exposure to life's disasters. These factors make death notifications and dealing with the survivors both vitally important and extremely difficult. These strong reactions magnify both the importance and the difficulty of death notifications.

INTERACTING WITH SURVIVORS

Even though notifying survivors of a loved one's death is one of the most difficult parts of their job, emergency clinicians rarely are taught the skills necessary to perform this task. Death notifications are emotionally draining: 70% of emergency physicians find notifying survivors to be personally difficult. This is not surprising given the results of one study that found only one-half of them received any type of death-notification education in medical school and only one-third received any such training during residency (2). This educational deficit occurs even though there are roughly 2.5

million deaths in the United States annually, with about one-third of them occurring in EDs (3).

TELEPHONE NOTIFICATIONS

The first interaction after a sudden, unexpected death may occur when emergency medicine personnel contact the survivors (4). This often must be done via telephone. Yet, this can be problematic, not only because the telephone call has to convey shocking and unexpected news, but also because the caller and the recipient are strangers. The person designated to make the call should first identify him- or herself and establish the identity of the person with whom he or she is speaking. Always deliver the news to an adult and try to determine whether someone is present to provide emotional or physical support.

One question consistently arises: Should emergency medicine personnel notify someone of a death by telephone? Most Americans, especially if they live nearby the hospital, prefer to be told that the patient is "critical," and then to be told of the death when they arrive at the hospital. Thus, callers are often advised to say that the patient is in critical condition and that their presence is requested. The caller should slowly recite any necessary contact information and tell the recipient to write it down; then they should have them repeat it back. However, if the recipient demands to know whether the person is dead, the notifier must answer the question truthfully. The majority of those who wish to be told immediately are men.

When calling relatives outside of the local area, tell them of the death. They should never be put in a position of rushing to the side of a "critical" or "dying" relative who is already dead.

If no one is at home, or if no adult is present, the notifier should leave a message. The only information appropriate to leave on a telephone or electronic (i.e., text, email) message system is the message that a specific person, identified by name or position (e.g., the son of George White), should return the call as soon as possible. Leave the name and telephone number of someone who will be available for the next 24 hours and who should have information

about the death. This may require providing a telephone number for the main ED (with instructions to ask for the charge nurse) or for the hospital's chaplain or social worker. Within the hospital or the ED, there should already be a system for each shift to pass on relevant information to the next. Protocols and other materials (English and Spanish) are available to teach and to aid emergency medicine telephone notifiers (4–8).

MEETING SURVIVORS: THE &LDQUO;FAMILY ROOM&RDQUO;

When survivors arrive, a medical staff member, chaplain, social worker, or specially trained volunteer should be available to meet them immediately. Such greeters usually were not involved in the resuscitative effort (9). They should memorize an introductory message to use when meeting survivors. The format will always be the same; only the specific information changes. Here is one example:

Mr. and Mrs. Smith? I'm [greeter's name and position]. The paramedics brought your son to the emergency department after he was involved in a bad car crash. The trauma team that has been working on him tells me that he was found unconscious and has not awakened. I'm not sure about his other injuries. We're going to go to a quieter area and I'll get someone from the team to speak with you (4).

The key points to remember when delivering this message are to identify the survivors, identify the ED representative, give only basic information, and guide the survivors to a quiet place. This quiet or "family" room is a place wherein survivors can wait until someone needs them (e.g., to give them updates on resuscitative efforts or the news about the death) and wherein they can have some privacy to grieve. All EDs should have a dedicated family room equipped with comfortable seating, tissues, and a telephone with long-distance access (4).

VIEWING RESUSCITATIONS

Traditionally, survivors have not been permitted to view resuscitation attempts. That attitude, however, is gradually giving way to a more enlightened view.

The argument against allowing survivor onlookers has been that resuscitations often involve large teams with too many people and unclear communications, and with team leaders who are unwilling or unable to make firm, timely, and rational decisions (10). Having family members present supposedly adds another complication and introduces the possibility of legal consequences stemming from an onlooker fainting, or otherwise becoming another patient. Those objecting to survivor presence during resuscitations have also raised concerns about correctly identifying survivors and about patient privacy, especially in light of HIPPA (the Health Insurance Portability and Accountability Act of 1996). They also are concerned that survivors may misinterpret the team's discussions or actions. Finally, team members may feel that family members will judge their actions (11). Emergency medical systems personnel, however, routinely encounter this during resuscitative attempts.

Despite such concerns, studies in both the United States and Britain have shown that nearly all survivors who witnessed emergency medicine resuscitative efforts found the experience helpful. As John Jesus wrote, "Resuscitation efforts may actually benefit families more than they have the potential to benefit the patients" (11). Many survivors (76%) thought that witnessing the resuscitation facilitated their grieving, and 64% felt that their presence was helpful to their dying family member (12). Psychological tests of survivors who witnessed resuscitation attempts, performed at 3 and 9 months after the event, showed that this group had fewer episodes of "intrusive imagery," such as flashbacks of the events leading to the death, than did those not present at the resuscitation (relatives in the control group). They also had lower levels of anxiety, depression, posttraumatic avoidance behavior, and grief (13).

The American Heart Association now endorses giving family members the opportunity to be present as long as the patient has not previously objected. This position stems from the benefit

families can derive from their presence during resuscitation attempts, the lack of harmful effects on them from viewing these resuscitations, and their quasi-right to be there based on the nature of their relationship to the patient (11,14,15).

Moreover, the presence of these survivors does not hinder the resuscitative efforts and often leads to quieter, more effective team efforts. Concerns about properly identifying survivors is misplaced, since physicians, as well as EMS personnel, can rely on the "reasonable reliance" concept (what a prudent person would believe and act on). In addition, HIPPA permits revealing health information about unconscious patients to family if there is an expectation that the patient would approve. Finally, while physicians may not bear legal responsibility for syncope survivors, having a staff member accompany them and ensuring that they are seated is good practice (11).

Experience has shown that survivors who witness ED resuscitative attempts never question whether the team "tried hard enough," do not ask whether the person is *really* dead, and spend less time in the ED trying to come to terms with the death. Moreover, survivors may actually thank the emergency medicine team for their efforts, a situation that rarely occurs under other circumstances, and the emergency medicine staff never has to "notify" survivors of the death.

The general procedure is as follows:

1. Ask survivors whether they want to view resuscitative efforts.
2. If they do, quickly brief them about what they will see, and assign a knowledgeable staff member (usually a chaplain, social worker, or ED nurse) who can answer their questions to accompany them.
3. Provide a chair so they can sit, particularly if they are elderly, and allow them to leave and re-enter as they wish.
4. Staff should attempt to cover as much of the patient as is compatible with effective resuscitative efforts.
5. Advise team members that family is in the room.
6. Encourage the survivors to talk to and touch the patient.

7. Decisions to pronounce the patient dead, while often discussed with the family, are generally announced by telling them "we must stop now." Never ask family members whether to stop the resuscitative effort; this is purely a medical decision.

Experience shows that the process of having key survivors view resuscitations often works best if EMS personnel notify the receiving hospital in advance of such a request. This allows the emergency medicine team time to decide whether they will permit it (if it is not policy), to advise team members, and to designate someone to escort the relative to the resuscitation room at the appropriate time.

If the family is present when it is clear that resuscitative efforts should cease, explain this to the family before supportive measures are discontinued. This provides them with a chance to "say good-bye" before the death is pronounced. Such procedures are standard in most pediatric EDs, as well as for pediatric resuscitations performed in the majority of general EDs.

NOTIFYING SURVIVORS IN THE ED

When key survivors have not witnessed resuscitation attempts, the most common postresuscitative scenario in EDs is that emergency medicine personnel must inform survivors of the death. But, unlike the relationship found in most in-hospital patient deaths, the emergency medicine personnel usually have had no chance to establish a "bond" with the survivors. Instead, they must quickly establish survivors' confidence in them while at the same time delivering devastating news. Staff should project an image of one "who has the information" rather than acting authoritatively or coercively. Emergency medicine staff should strive to eliminate any perception of racial, social, or cultural differences between them and the survivors, as this may lead to a sense of distrust (16).

One technique medical personnel often use to deliver the news about sudden unexpected death is that of "presaging," or leading up to this news by dribbling out bits and pieces of bad information over a very short period of time. Also called "hanging crepe," this

technique allows survivors to gradually understand that something very bad has occurred.

"How much emotion should I show when delivering the news?" is a frequently asked question. During resuscitative attempts, caregivers must put their emotions "on hold" to perform their duties in the most effective way for the patient. If the resuscitation is unsuccessful, it is okay to express some emotion when delivering the news of the death to survivors, but staff must retain enough control to help and support the family.

BARRIERS TO EFFECTIVE ED NOTIFICATIONS

Emergency medicine personnel are at a distinct disadvantage when dealing with survivors of sudden unexpected deaths. First, the physicians and nurses in emergency medicine are usually aggressive, action-oriented people who want to see an instantaneous return for their expended energies. They often see a patient's death as a personal failure—an assault on their sense of accomplishment and satisfaction—and respond accordingly (17). In addition, except in rare instances, they have never met either the deceased patient or the survivors. Other barriers are listed in Table 169.1.

TABLE 169.1
Barriers to Effective ED Death Notification

No pre-existing relationship with medical staff
Survivor stress: fear, grief, remorse, anxiety, panic
Time: Staff has limited time, needs to treat other patients/crises, and may be interrupted to make other decisions
Strange environment: surroundings, noise, smells, lack of privacy
Survivor status/behavior: anger, inebriation, disbelief, not available
Cultural or language differences
Medical staff stress: must deliver bad news, ask for autopsy (or notify about medical examiner requirements), ask for organ/tissue donation, and allow time in the midst of other patients' emergencies
Medical staff anger: decedent caused other injuries or deaths
Uncertainty: often not clear about the exact cause or manner of death
Sense of failure: "losing" a patient often pervades discussions

Reproduced with permission from Iserson KV. *Grave Words: Notifying Survivors about Sudden, Unexpected Deaths*. Tucson, AZ: Galen Press; 1999.

Resuscitative efforts effectively halt most other activity in the majority of EDs. Once resuscitation is terminated, the clinicians may be overwhelmed by the onslaught of other patients whose problems demand their immediate attention. Because of this backlog of sick patients who have been ignored during the resuscitative attempt, survivors are often given too little attention. Compounding this is the fact that emergency physicians' coping mechanism is often to immediately return to normal work activities (18).

SURVIVOR REACTIONS

Intervention strategies to facilitate survivors' grieving processes may help them avoid significant future psychiatric sequelae. Survivors' overall reactions are variously described as grief, mourning, and bereavement. *Grief* denotes the intense emotions and physical symptoms associated with the loss. *Mourning* is a social expression of grief. *Bereavement* is the total normal response to loss.

Grief is a normal process initiated by major personal loss, such as the loss of a spouse, parent, child, or significant other. Grieving is characterized by an intense, in-depth review of the survivor's relationship with the decedent. A grieving person repeatedly reviews memories of the decedent and only gradually confronts each one with the realization that it no longer corresponds to something

real. The grief response may also include physical ailments and guilt, such as feeling responsible for the death or for failing to resolve interpersonal conflicts with the decedent (Table 169.2). This process continues until the grieving person is gradually reconciled to the loss. Grieving serves the psychological purposes of breaking emotional ties with the decedent and reestablishing attachments to living persons. Most survivors' symptoms resolve without the need for specific professional interventions. Some EDs have invited survivors back to answer their questions several months after the death, although whether this is beneficial remains uncertain (19).

TABLE 169.2
Common Grief Reaction Symptoms and Statements

1. **Denial**
   - Loneliness
   - Agonizes over the death
   - Wants to die
   - Feels hopeless
   - I should have died instead
   - Never be happy again
   - Little control over sadness
   - Frequently cries
   - Somnambulism
   - Heaviness in heart
   - Difficulty accepting death's permanence
   - Feels like I am in shock

2. **Panic Behavior**
   - Panic attacks
   - Heart beats faster; dizziness
   - Frequently frightened; startle easily
   - Frequent muscle tension
   - Dyspnea, fatigued, shaky
   - Feels sick more often; headaches; back pain
   - Burning in stomach
   - Worries excessively

3. **Blame and Anger**
   - Frequently feels bitter, resentful
   - Feels revengeful
   - Hostile feelings; gets angry often
   - Blames/wants to harm others

4. **Detachment**
   - Feeling worthless; without confidence
   - Confused about who I am
   - Feels unable to cope
   - Don't know myself
   - Afraid I will lose control
   - Feels detached
   - Avoids tenderness

5. **Disorganization**
   - Forgets new information
   - Forgets easily: names, numbers
   - Difficulty concentrating, remembering, thinking
   - Tasks are insurmountable

Note: "Personal growth" is a subsection of this checklist. Individuals at this stage are unlikely to present to EDs with symptoms related to grief or bereavement.

Adapted from Hogan NS, Greenfield DB, Schmidt LA. Development and validation of the Hogan Grief Reaction Checklist. *Death Stud*. 2001;25:1–32.

Grief expressions are determined by cultural mores (20). Some people express grief histrionically, with loud crying and sobbing, whereas others remain still, with little visible emotion. Although they display no overt signs, survivors may be deeply affected and grieving over the death (21). Several responses can be perplexing and may be misinterpreted by staff. A frequent initial reaction is denial, a psychological defense that closes off perceptions of painful immediate reality. The survivor may question the physician closely for proof of the decedent's identity or may continue to refer to the decedent as if he or she were alive (22). At other times, survivors display antagonistic and angry feelings toward staff members, accusing them of being negligent or of not doing all they could have done. This anger often represents the survivors' own unconscious anger toward the decedent for abandoning them, or it may stem from guilt about unresolved conflicts with the decedent.

Emergency medicine professionals may have difficulty in coping with initial survivor reactions, such as withdrawal (inaccessible, mute, refuses to listen), denial (of fact, feelings, reality), anger (directed at nurse, doctor, self), isolation (feelings of aloneness), bargaining ("I'll pay anything not to have . . ."), inappropriate responses, guilt, and crying. Although emergency medicine personnel often fear physical violence toward the notifier, this rarely occurs. However, violence harmful to a survivor, such as punching a wall, or among survivors is common. Teenage boys and young adult men seem to be the most prone to expressing their grief in these self-destructive manners.

Educate survivors about the symptoms of grief and reassure them that these symptoms are normal. Depressed mood, sleep disturbance, crying, difficulty with concentration, loss of interest, anxiety, and weight loss are the most common symptoms (23). Provide anti-anxiety or hypnotic medications to survivors only if requested and only after a formal evaluation of the individual involved. Limit the supply to that needed for only a few days.

Arrangements should always be made for other family members or friends to stay with a survivor for the next 24 to 48 hours, because suicide is a possibility, especially for a spouse who has been married for many years (24,25). If a survivor appears to be suicidal or homicidal, ask them about this and, if appropriate, obtain a formal psychiatric consult.

Support groups may help some survivors. The ED should have a preprinted list of telephone numbers and addresses of local and national support groups that they can give to survivors.

VIEWING THE BODY

Identifying the patient can be very difficult in some cases. Many patients needing resuscitation arrive in the ED without identification, usually either because they had none available or because the police have it. Care must be taken to corroborate the decedent's identity before any survivors are notified. To do this, emergency medicine personnel or the investigating officers may have to ask survivors about their relative's general characteristics (height, skin, and hair color), identifying marks (scars, tattoos, birthmarks), or deformities (prior amputations).

Making decedent identifications is vital after disasters such as the World Trade Center attacks or 2004 Southeast Asian tsunami, in which many bodies are missing or unidentified. Survivors may feel "emptiness, frustrated or unresolved grief" that can be partially assuaged only by identifying the dead (26–28).

In the ED, offer survivors the opportunity to view the body (4). Viewing the body facilitates the grief reaction. If they are reluctant or unwilling to do so, do not make them feel that their decision is wrong. Many survivors prefer not to view the body (29). Never refer to the decedent as "the body" or "it." Instead, use the person's proper name or a personal pronoun. Warn survivors about the visible effects of trauma and resuscitation, and also of postmortem skin changes such as cyanosis or livor mortis.

Prepare the body for ED viewing. Remove blood and emesis before family members see the body. Describe any medical

equipment that must be left in place until the medical examiner completes the necessary postmortem examination and explain why it is still there (30). Cover the body with a sheet or blanket, but leave the head and hands exposed for the family to touch, and encourage them to do this. Move the body to a private room, if possible. Let them cut off a lock of hair, if requested. Allow family to be alone with the body, unless there are legal reasons (e.g., ongoing police investigation) for not doing so. Staff should remain available nearby, but outside the room, to provide support to the family. Most family members will leave within 15 minutes.

MAKING FINAL ARRANGEMENTS

Part of death notification involves answering survivors' questions in a knowledgeable manner. To do this requires knowing something about body disposition options, medical examiner/coroner laws and procedures, and organ and tissue donation (30–32). These subjects are rarely discussed in medical or nursing curriculums.

After the family has viewed the body, it is then appropriate to have them to sign any necessary documents (4,22). Many survivors are concerned about postmortem paperwork, so having an experienced person guide them through the process is very useful (29). Offer the use of a telephone to call a funeral home. Ask again if there are any questions. Generally, no question should remain unanswered, unless the information is unavailable. Tell them how to reach you if they have questions at a later time.

Explain the roles of medical examiners and the police in cases of sudden, unexpected, or violent deaths and how the decedent's belongings will be handled. If you will be signing the death certificate, tell them the cause(s) of death that you will list. If an autopsy is mandatory, as it is in many ED deaths, explain that the medical examiner will determine the cause of death at a later time. If the cause of death is unclear, autopsy results will be helpful, inform the family of this and ask them for permission for an elective autopsy (30).

The issue of organ and tissue donation should be broached before family members leave the hospital; in fact, most states require that this option be addressed. Two ways to broach the subject are to ask, "Has your family ever discussed organ or tissue donation?" or "Our hospital offers organ and tissue donation. Would you like to discuss this further with someone from the transplant program?" If the family expresses an interest, contact the appropriate agency immediately.

Have lists of clergy and housing accommodations available for out-of-town survivors. Unless personal effects and clothing removed from the body are needed by the medical examiner or for a police investigation, these should be given to survivors. Advise them of the condition of clothing and place it in a paper or plastic belongings bag; never use a trash bag. Tell survivors when they have completed everything they need to do and that they may leave whenever they like. The physician or a designated staff member should accompany the survivors to the door.

DEATH-NOTIFICATION EDUCATION

Although it is rarely done (4,33), educating emergency medicine professionals about sudden-death notification is vital, as doing it poorly can adversely affect both the survivors and the healthcare professionals involved. Such education succeeds when it is combined with direct observation during actual death notifications, subsequent evaluation, feedback and, when necessary, further education (34). Educational resources and materials to help remind ED staff of the steps involved are available (4–8,32,35).

The easiest and most effective way to provide this education is to add a module to the resuscitation courses that emergency medicine personnel must take on a periodic basis (34). Such education can help the staff deal with their own emotions (e.g., feelings of defeat, guilt, impotence, and incompetence) and fear of death, and with survivors' reactions. It can also help avoid the common problem of emergency medicine staff trying to reduce their own stress by delaying the news, thus increasing the family's anxiety, or by

rushing into the room unprepared and presenting the news in an awkward manner.

A staff that is aware of the dynamics of grieving and of survivors' needs can facilitate the grief process, cushion the trauma of loss, and establish a basis for a healthy grief response (4,36).

Common Pitfalls

- Poor communication.
- Remarks such as "Everything will be okay" or "It was God's will," which may prematurely seal off the grief response.
- Failing to use a "D" word (Death, Dead, Died) to clearly indicate that the patient has died.
- Not allowing and encouraging survivors to express their feelings.
- Impeding or impairing survivors' ability to grieve by routinely prescribing medication.
- Failing to address survivors' support systems.
- Not offering family members the option of organ and tissue donation.

SECTION XVII
Dermatologic Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 170

Life-Threatening Dermatoses

Kenneth J. Neuburger

Cutaneous lesions are often the first clinical sign of serious systemic disease. In this chapter, the focus is on the recognition and acute management of the common life-threatening dermatoses listed in Table 170.1. These disorders can be conveniently grouped into diffuse red rashes, vesiculobullous eruptions, localized or discrete lesions, and purpuric or hemorrhagic lesions (Table 170.2). The following dermatologic findings should alert clinicians to a potentially serious eruption (1):

- Confluent erythema
- Facial edema or central facial involvement
- Skin pain
- Palpable purpura
- Skin necrosis
- Blisters or epidermal detachment
- Positive Nikolsky sign
- Mucous membrane erosions
- Urticaria
- Swelling of tongue

Several entities are not discussed in detail here but deserve brief mention. *Palpable purpura* is a skin manifestation of vasculitis; it is not a manifestation of thrombocytopenia or clotting disorder. Involvement may be limited to the skin or may be systemic. Treatment is for the underlying vasculitic disorder.

TABLE 170.1
Life-Threatening Dermatoses

Diffuse Red Rashes
- Urticaria with anaphylaxis[a]
- Toxic shock syndrome[a]
- Kawasaki disease
- Toxic epidermal necrolysis[a]
- Staphylococcal scalded skin syndrome[a]
- Generalized exfoliative erythroderma[a]
- Pustular psoriasis
- Cutaneous T-cell lymphoma[a]
- Systemic lupus erythematosus

Localized or Discrete Lesions
- Erysipelas and cellulitis[a]
- Gonococcemia[a]
- Ecthyma gangrenosum[a]
- Brown recluse spider bite
- Behçet syndrome
- Malignant melanoma[a]
- Kaposi sarcoma and AIDS[a]
- Basal cell carcinoma[a]
- Squamouus cell carcinoma[a]

Vesicobullous Diseases
- Pemphigus[a]
- Pemphigoid[a]
- Stevens–Johnson syndrome[a]
- Toxic epidermal necrolysis[a]
- Disseminated zoster
- Disseminated herpes simplex

Purpuric or Hemorrhagic
- Meningococcemia[a]
- Gonococcemia[a]
- Disseminated intravascular coagulation
- Palpable purpura[a]
- Brown recluse spider bite
- Rocky Mountain spotted fever[a]
- Miscellaneous hematologic disorders

[a]Discussed in this chapter.

TABLE 170.2
Identification of Life-Threatening Diseases Associated with Fever and Rash

Disease	History	Characteristics of Rash	Distribution of Rash	Associated Clinical Findings	Diagnostic AIDS
Rocky mountain spotted fever	Tick exposure (75%) May–September in temperate zone states Heaviest endemic area: middle Atlantic states and Southeast	Initial maculopapular petechiae appearing on second to sixth febrile day and usually painless	Begins on wrists, ankles, forearms, spreading within 6–8 hrs to palms, soles, trunk	Prodrome of fever, headache, myalgias Hyponatremia, normal to slightly increased WBC, thrombocytopenia, hypoalbuminemia	Biopsy of involved skin with immunofluorescence and other serologic tests. Serology: Complement fixation more sensitive and more specific than Weil–Felix agglutination
Meningococcemia	Tends to occur in late winter, early spring Outbreaks in military recruits, crowded living conditions	*Acute:* May be maculopapular initially. Small petechiae with irregular borders (smudging), at times with vesicular or grayish ulcer. May coalesce. Painful *Chronic:* Maculopapules, petechial vesicles, or pustules; tender nodules	*Acute:* Extremities and trunk in random fashion *Chronic:* Extremities, particularly over joints	*Acute:* Meningitis, disseminated intravascular coagulation, shock, acidosis *Chronic:* Rash appears with recurrent cycles of fever over 2–3 mos	*Acute:* Aspiration of center of skin lesions for Gram stain, culture (up to 60% positive). Blood cultures Cerebrospinal fluid culture and Gram stain *Chronic:* Blood culture usually positive during febrile episode. Biopsy findings resemble leukocytoclastic angiitis
DGI	Incidence higher in women than in men Young, sexually active Onset often related to menstruation	Pustules on erythematous base most characteristic. Also, macules, papules, pustules, and bullae less commonly	Over extremities, with relative sparing of face and trunk; usually few (5–40) lesions	Migratory polyarthralgia, tenosynovitis, septic arthritis	Gram stain of lesion Blood, joint fluid culture (50%) prove diagnosis Cervical, rectal, throat cultures support diagnosis
Pseudomonas septicemia	Hospitalized patients, especially with neutropenia or burns	*Vesicles:* Isolated or in small clusters rapidly becoming hemorrhagic *Ecthyma gangrenosum:* Round, indurated, ulcerated painless lesion with central gray eschar *Maculopapular lesion:* Small erythematous lesion resembling "rose spots" Gangrenous cellulitis	Random Axillary or anogenital area, thigh Trunk Localized	Generally extremely toxic, with fever; septic picture	Aspiration of lesions for Gram stain culture Cultures of blood, urine, sputum, etc.
Toxic shock syndrome	Young female predominance, especially with menses Rare in men 1–4 d prodrome of fever, myalgias, arthralgias, and diarrhea	*Erythroderma:* Seen at presentation Diffuse, blanching, macular (deep-red "sunburned" appearance) Resolves within 3 d, followed 5–12 d later by desquamation, most commonly of hands and feet *Mucosal hyperemia:* Pharynx, conjunctivae, vagina	Diffuse, hands and feet predominantly	Fever, severe hypotension, multisystem involvement (GI, muscular, renal, hepatic, hematologic, CNS)	Clinical criteria (see Chapter 148) Identification of toxin producing strain of *S. aureus* Negative serology for RMSF, leptospirosis, measles

CNS, central nervous system; RMSF, Rocky mountain spotted fever.
Reproduced with permission from Stein JH, ed. *Internal Medicine*. 5th ed. St Louis, MO: Mosby; 1998:1382.

Generalized exfoliative erythroderma (formerly called exfoliative dermatitis) is a diffuse, widespread dermatitis that covers most of the body surface. This condition not only causes pruritus and pain but may be complicated by hypothermia; fluid, electrolyte, and protein loss; invasion of bacteria and opportunistic organisms through the skin; and high-output congestive heart failure secondary to severe vasodilatation. The causes of exfoliative erythroderma include previously existing skin diseases (e.g., psoriasis, atopic eczema, contact dermatitis) (50%); drug eruptions (10%); lymphoproliferative disorders (e.g., Hodgkin disease, leukemia, Sézary syndrome) (15%); and idiopathic (25% to 40%). Mortality is $<5\%$.

Other potentially life-threatening entities, such as angioedema (see Chapter 176) and disseminated herpetic infection, are discussed in other chapters.

Finally, a brief discussion at the end of the chapter focuses on the recognition of the various types of skin cancer.

DIFFUSE RED RASHES

Staphylococcal scalded skin syndrome (SSSS) (Fig. 170.1) occurs in children and, rarely, adults and is caused by an exotoxin from an

infecting strain of coagulase-positive *Staphylococcus aureus*. The disease may present as a prodrome of fever, irritability, malaise, and exquisite skin tenderness; in other cases, the child presents with the sudden onset of generalized erythema. The skin is red, warm, and very tender. Ill-defined, flaccid bullae then desquamate in large sheets. Gentle lateral stroking of the skin causes the epidermis to separate (Nikolsky sign).

Therapy consists of systemic antibiotics effective against methicillin-resistant *Staphylococcus* (due to its increased incidence). Children older than 1 year and with mild symptoms may be treated as outpatients. Children who appear toxic and infants should be admitted. Despite proper treatment, most of the superficial body surface will desquamate but, because the site of blister cleavage is in the superficial layer of the epidermis, healing occurs rapidly over 7 to 14 days.

Toxic epidermal necrolysis (TEN) (Fig. 170.2) is a disease of adults in which the skin also sloughs in large sheets. Although it is very similar in appearance to SSSS, it is quite different. It has been accepted that erythema multiforme, Stevens–Johnson syndrome (discussed later in the chapter), and TEN are a progression of severity of the same disorder (2). All usually start with a prodrome of fever, malaise, and myalgia. The skin is initially diffusely painful, hot, and red. Within days, blisters and large areas of denuded skin develop; erosive, sloughing lesions of the oral mucosa are common. The Nikolsky sign is positive.

The differences between TEN and SSSS are noteworthy. SSSS almost always occurs in children and is secondary to staphylococcal infection. TEN almost always occurs in adults and is most often precipitated by drugs such as phenytoin, carbamazepine, lamotrigine, phenobarbital, antibiotic sulfonamides, allopurinol, and nonsteroidal anti-inflammatory agents (3). About 62% are probably caused by medications, 23% possible, and the other 15% unlikely to be drug related (3). Mucous membrane involvement in SSSS is rare and limited to the lips but, in TEN, erosive oral lesions are common. Although SSSS sloughs only the superficial layers of epidermis, TEN desquamates the entire thickness of the epidermis, accounting for the

high associated mortality rate. The mortality rate in SSSS is very low, whereas that of TEN can be >50%.

The diagnosis of TEN is made by clinical presentation and confirmed by biopsy. Treatment is removal of the precipitating agent, if possible, and consists of judicious fluid, electrolyte therapy, and prevention of infection (4). Early transfer to a burn center is standard of care (4). There are conflicting studies concerning use of intravenous immunoglobulin (IVIG) in the therapy for TEN (4). IVIG, if used, should be started early in the course at doses of 1 g/kg daily (5) up to 2 to 3 g/kg daily for 4 to 5 days (4,5). Corticosteroid treatment is being reevaluated as it may or may not be useful depending on dosing, and time of use in the disease process. There are case reports of rapid improvement with cyclosporine, administered 3 to 10 mg/kg daily for 8 days to weeks (4,5). Plasmapheresis, antitumor necrosis factor therapy, and *N*-acetylcysteine treatments show some promise, but need further study (4,5).

FIGURE 170.1 Staphylococcal scalded skin syndrome. A 10-day-old Caucasian boy with staphylococcal scalded skin syndrome. He was treated with fluids, oral dicloxacillin, and wound care. His skin healed completely and without scarring within 2 weeks of this photograph being taken. (From Avery GB, Fletcher MA, MacDonald MG. *Neonatology: Pathophysiology and Management of the Newborn.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:1199, with permission.)

Toxic shock syndrome (TSS; see Chapter 192) is an acute, febrile illness originally associated with localized infection by strains of *S. aureus* that produce an exotoxin (TSST-1) (6) that results in the clinical signs and symptoms. Currently enterotoxins A, B, C, G, H,

and I have also been implicated in causing TSS (6,7). Characteristic signs and symptoms include an early macular rash, hypotension, abnormalities in multiple organ systems, and acral desquamation occurring 1 to 2 weeks after the onset of the illness (Fig. 170.3). Originally about 90% of the *S. aureus* isolates from patients with TSS produce the exotoxin. Eighty-five percent to 90% of cases were reported in menstruating women (6,8). In fact, the disease was originally described in association with the use of highly absorbent vaginal tampons that could be kept in place for many hours before being discarded (6). Other cases are associated with localized infection in men, children, and nonmenstruating women (9). A new population assessment was done in 2000–2006 with 61 cases (33 menses related and 28 other sites). TSST-1 was found in 80% of isolates and more prevalent in menstruating than nonmenstruating situations (89% vs. 50%). Enterotoxins A, B, and C were found more often in nonmenstrual infections versus menstrual (100% vs. 25%). Methicillin-resistant *S. aureus* (MRSA) was found in four cases (8).

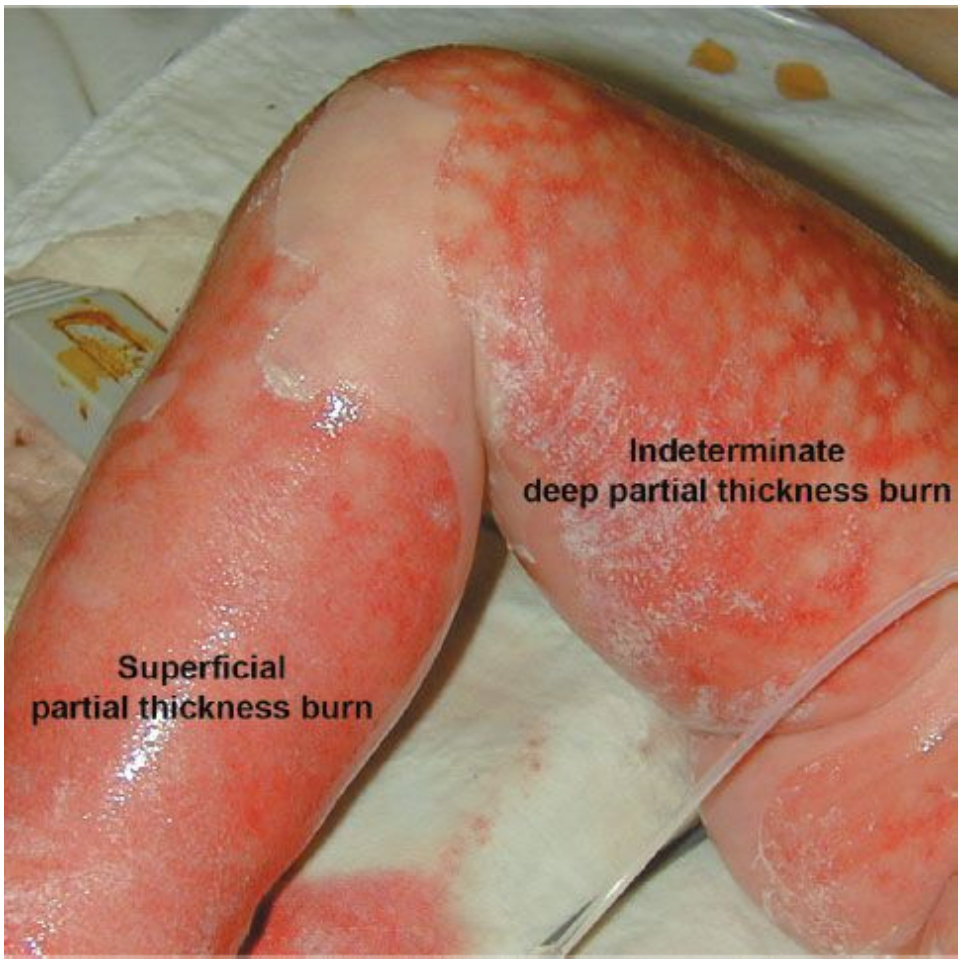

FIGURE 170.2 Toxic epidermal necrolysis that may extend into the reticular dermis (deep partial thickness) or the papillary dermis (superficial partial thickness). The peripheral zone of hyperemia correlates with a superficial or first-degree burn and might be similar to a sunburn. (From Mulholland MW, Lillemoe KD, Doherty GM, et al. *Greenfield's Surgery Scientific Principles and Practice.* 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

FIGURE 170.3 Toxic shock syndrome. Desquamation of the skin of the palm in a patient with staphylococcal toxic shock syndrome. (From Sweet RL, Gibbs RS. *Atlas of Infectious Diseases of the Female Genital Tract*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005, figures 9–2.)

The early cutaneous rash is scarlatiniform and blanches with pressure; it can be difficult to appreciate because it is often quite pale. Coincident with the rash, there is often erythema of the mucous membranes of the oropharynx, conjunctivae, and vagina. Desquamation of the skin of the distal extremities occurs 1 to 2 weeks after the onset. Hair and nail loss follows 1 to 2 months later.

Strict criteria for the diagnosis of TSS are fever, hypotension or orthostasis, an erythematous macular rash, involvement of at least three organ systems, and the presence of an *S. aureus* infection. Most patients have facial and extremity edema. The illness can proceed rapidly. Hypotension may appear early; most patients present to the hospital with at least orthostasis.

The differential diagnosis of TSS includes Rocky mountain spotted fever (RMSF), scarlet fever, sepsis, Kawasaki disease (rare in those older than 8 years), leptospirosis, Colorado tick fever (in which

photophobia is common), and other viral infections. Supportive treatment for dehydration and hypotension includes fluid replacement and the use of pressors, if necessary. The adult respiratory distress syndrome is common in serious cases.

Although it has not been proven that antibiotics are always necessary for recovery, provided the site of located staphylococcal infection is removed (e.g., removal of tampons or incision of abscesses). While awaiting culture results, treatment should cover MRSA. Vancomycin plus clindamycin, or linezolid alone are appropriate. Clindamycin and linezolid both decrease toxin production while vancomycin does not (9).

IVIG should be considered in those with a poor response to intensive therapy after several hours (less than 6 hours). The dosing is not well defined but should probably be greater than the original study dose of 1 g/kg the first day and 0.5 g/kg on days 2 and 3 (9). Because TSS recurs in a large percentage of women with tampon-associated TSS who continue to use tampons, women with a history of TSS should no longer use tampons. All symptomatic patients suspected of having TSS require admission for vigorous supportive treatment.

The hallmark of streptococcal TSS, first described in the mid-1980, is a relatively early onset of shock and multiorgan failure. The currently proposed criteria for streptococcal TSS are isolation of group A streptococci from a sterile or nonsterile site, hypotension, and at least two of the following: renal impairment, coagulopathy, liver function test abnormalities, adult respiratory distress syndrome, soft-tissue necrosis, and rash (which may be generalized macular or possibly scarlatiniform and may desquamate) (6,10). Treatment is with high-dose penicillin (20 to 24 million units/d); cephalosporins, clindamycin, erythromycin, vancomycin, and penicillinase-resistant penicillins are also effective. Cases with an indeterminate source should be treated as in staphylococcal toxic shock. Aggressive supportive care is mandatory, as is surgical drainage or debridement for abscess, pyonecrosis, or necrotizing fasciitis. Again, IVIG is recommended if an adequate response is not seen within 6 hours. The IVIG dose should be 1 g/kg on day 1 and 0.5 g/kg on days 2 and

3 (9). Even with prompt treatment, mortality ranges between 20% and 30%.

VESICOBULLOUS DISEASES

The spectrum of acute, self-limited immunologic reactions causing vesicles includes bullous erythema multiforme, Stevens–Johnson syndrome, and TEN. These are probably the same disease with increasing severity and more skin and mucous membrane involvement (11). The causes are the same as those listed in the previous discussion of TEN, although erythema multiforme can be related to herpes simplex and mycoplasma, and Stevens–Johnson syndrome is usually related to drugs. The classic lesion of erythema multiforme is the target lesion, a central gray wheal or bulla surrounded by concentric rings of erythema and normal skin. As the name implies, however, many types of lesions may be present simultaneously: macules, papules, urticaria (though non pruritic), and bullae. The extremities are involved more than the trunk; the palms and soles are often affected. The rash appears abruptly and may be accompanied by fever, malaise, and pruritus.

Farther along the spectrum is bullous erythema multiforme, with less than 10% skin involvement and target lesions, followed by Stevens–Johnson syndrome, with 10% to 30% skin involvement (11) accompanied by constitutional symptoms and affecting at least two mucous membranes. A prodrome of fever, malaise, and myalgia is followed by the explosive appearance of blisters on mucous membranes and skin. Symmetric blistering begins on the dorsa of the hands and feet and on extensor surfaces. Erosive lesions begin on oral mucosa, lips, and bulbar conjunctiva and can extend to the pharynx, larynx, esophagus, and genital mucosa (Fig. 170.4). Ocular lesions can result in corneal ulceration, panophthalmitis, and even blindness, requiring early recognition and treatment. The prognosis of Stevens–Johnson syndrome is usually good (7). However, the disorder may progress to an illness clinically indistinguishable from TEN, with large confluent bullae and sloughing of epidermis in sheets.

FIGURE 170.4 Stevens–Johnson syndrome. Erythema multiforme major (Stevens–Johnson Syndrome). Bullae and crusts are noted on the lips, and targetoid lesions are seen on the hand. (From Goodheart HP, MD. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Milder cases of Stevens–Johnson syndrome can be treated with oral antihistamines and topical corticosteroids; more severe cases require hospital admission. More severe cases can be treated as noted for TEN earlier in the chapter. Corticosteroids, antitumor necrosis factors and *N*-cetylcysteine need to be further evaluated before they can be recommended for treatment (4,7).

PEMPHIGUS VULGARIS

Pemphigus vulgaris, a rare disease, occurs mostly in adults 40 to 60 years old and is distinguished from other blistering diseases by its fulminant course. Early identification and aggressive treatment may avert a poor outcome. Initially, blisters may be localized to small areas of the mucous membranes or skin; lesions may be present for months before the blistering becomes generalized. The lesions are typically painful flaccid bullae that may rupture easily or painful erosions where bullae have ruptured (Fig. 170.5). They have a

predilection for the scalp, face, chest, axillae, and groin. These painful erosions or collapsed bullae can persist despite successful treatment of skin lesions. The Nikolsky sign is positive. Half of patients present initially with oral lesions; 90% have oral lesions at some time during the course of the illness.

FIGURE 170.5 Pemphigus vulgaris. **A:** Bulla. **B:** Erosion. (From Berg D, Worzala K. *Atlas of Adult Physical Diagnosis.* Philadelphia, PA: Lippincott Williams & Wilkins, 2006.)

The diagnosis of pemphigus is made by biopsy of intact skin adjacent to a bulla. Direct immunofluorescent staining for antiepithelial antibodies localized to the epidermal cell membrane is confirmatory. Indirect immunofluorescence of the patient's serum or blister fluid detects a pemphigus antibody that reacts with epithelial cell membranes of most species. Therapy is with corticosteroids, and immunosuppressive agents.

Bullous pemphigoid is an autoimmune blistering disease occurring mostly in the elderly. The bullae of bullous pemphigoid, unlike those of pemphigus vulgaris, are tense rather than flaccid, and oral lesions are less common The Nikolsky sign is negative. Bullous pemphigoid

is characterized by spontaneous remissions and exacerbations and a low mortality rate; most patients experience complete remission. As with pemphigus vulgaris, the diagnosis is made by biopsy of the skin adjacent to a blister. Direct immunofluorescence studies reveal antibodies bound to the basement membrane; these antibodies can often be found in the serum as well. Mild cases are treated with topical corticosteroids or intralesional injections; severe cases require systemic corticosteroids with or without immunosuppressive agents.

LOCALIZED OR DISCRETE LESIONS

Patients with gram-negative sepsis may manifest the skin lesions known as *ecthyma gangrenosum* (Fig. 170.6). Originally described in *Pseudomonas* septicemia, they may also occur with bacteremia due to *Escherichia coli* or *Klebsiella* and have been reported in the absence of disseminated infection (12). Because the lesions of ecthyma gangrenosum are manifestations of life-threatening illness, the diagnosis must be made early. Ecthyma gangrenosum is a true dermatologic emergency; patients with it are critically ill and usually immunocompromised (e.g., with leukemia or lymphoma). Treatment with newer antimicrobial regimens for carbapenemase-producing organisms may be needed in select cases (13).

FIGURE 170.6 Ecthyma gangrenosum. (From Berg D, Worzala K. *Atlas of Adult Physical Diagnosis.* Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

The appearance of the lesion can vary, depending on the stage of the illness at presentation. Beginning as a painless macule or vesicle, it indurates and assumes the appearance of a pustule or bulla on a blue or red base. The lesion then sloughs, leaving a gangrenous ulcer, usually several centimeters in size. These solitary or multiple lesions usually occur mainly in the perineal region or on the extremities.

Disseminated gonococcal infection (DGI) usually occurs in individuals with asymptomatic infection of the pharynx, rectum, or genitalia. The patient commonly presents with fever, skin lesions, arthritis, periarthritis, tenosynovitis, or any combination of these signs. DGI occurs most commonly in women during menstruation or pregnancy, but it can occur in any patient with gonococcal infection.

The skin lesions are pustules or vesicles on an erythematous base about 5 mm in diameter, but they may also be petechial, bullous, papular, or hemorrhagic. These are usually relatively few (fewer than 10 to as many as 30), and they typically appear on the extremities and resolve rapidly (usually in <1 week). The periarthritis of DGI presents with joint swelling and tenderness, which are often transient and migratory. Septic arthritis occurs most commonly in the larger joints (knees, hands, ankles, and elbows, in descending order of occurrence). Complications such as endocarditis, meningitis, and sepsis are rare.

The diagnosis of gonococcemia (Fig. 170.7) is a clinical one. Any sexually active person with polyarthritis, tenosynovitis, and typical skin lesions can be given a presumptive diagnosis of gonococcemia with little doubt as to its accuracy. Gonococcal cultures or polymerase chain reaction (PCR) testing should be performed on specimens obtained from all mucous membrane surfaces and blood and (when appropriate) joint fluid. The diagnosis can also be made on the basis of a prompt response to empiric antibiotic treatment (see Chapter 184). Antibiotic treatment regimes include ceftriaxone 1 g IV or IM daily plus azithromycin 1 g orally or doxycycline 100 mg

twice daily for 7 days. It is important to follow the most current CDC recommendations closely, as resistance patterns change (14).

FIGURE 170.7 Disseminated gonococcemia. *Neisseria gonorrhoeae* may disseminate from mucosal surfaces via the bloodstream and produce arthritis/arthralgia and a rash. The most characteristic lesion is the hemorrhagic vesicopustule seen in the web space of the teenage girl's hand. There is a pustule on the sole of her foot. (From Fleisher GR, Ludwig W, Baskin MN. *Atlas of Pediatric Emergency Medicine.* Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)

The differential diagnosis should include Reiter syndrome (a syndrome of urethritis, conjunctivitis, and arthritis that usually occurs after a diarrheal illness, has dissimilar skin lesions, and does not respond to antibiotics); meningococcemia (which has more numerous petechial lesions); immune complex diseases (which may have joint manifestations but a different type of skin lesion); and rheumatic fever.

Admission is indicated only for patients with severe systemic signs and symptoms or severe joint involvement (especially of weight-

bearing joints) and those who cannot be followed closely as outpatients.

Erysipelas is a superficial cellulitis that progresses rapidly in extent and involves the associated lymphatic channels. The classically described offending organism is the group A streptococcus, but groups B, C, and G streptococci and *S. aureus* have also been isolated (15). The infection is most common in infants and children and in the elderly. The source in most cases is probably an inapparent wound. Erysipelas may range from a self-limited process that resolves spontaneously, even without antibiotics, to a rapidly progressive and severe infection leading to bacteremia. Admission is indicated for patients with extensive facial or neck involvement or for patients with fever and a toxic appearance.

The involved skin is erythematous, warm, and tender to palpation and has an advancing margin that is slightly elevated. Fever is common. The diagnosis is usually clinical, because local aspiration is rarely positive. Punch biopsy may be useful, but it is usually not readily available. The differential diagnosis includes cellulitis, maxillary or frontal sinus infections (if localized to the face), and erysipeloid (if localized to the hands).

Treatment with penicillin is rapidly effective if erysipelas is due to streptococci, but, because it is rarely easy to identify the causative organism, either a first-generation cephalosporin or a penicillinase-resistant penicillin should be used to cover methicillin-sensitive *Staphylococcus.* Clindamycin, vancomycin, or linezolid should be used if MRSA is possible, and may be used in the penicillin-allergic patient. Hospital admission is based on the patient's clinical status. Some affected individuals may be treated as outpatients with close follow-up and admitted if there is no response or any worsening after 1 to 2 days of oral antibiotic therapy.

Cellulitis, an acute, spreading inflammation of the skin and subcutaneous tissue, appears as a warm, tender, erythematous area with indistinct margins. Its differentiation from erysipelas is based on the appearance of the advancing edge of the infection. In cellulitis, the edge is not raised. In practice, the clinical management of patients with erysipelas and with cellulitis is similar. Erysipelas is

more likely, however, to require prompt initiation of antibiotic therapy because it can progress so rapidly.

PURPURIC OR HEMORRHAGIC LESIONS

Neisseria meningitidis colonizes the nasal mucosa in humans (5% to 15%) but may invade the bloodstream and cause disease. Most cases occur in children and adolescents, although any age group may be affected. The mortality of meningococcemia is higher than that of meningococcal meningitis.

Meningococcemia (Fig. 170.8) usually follows an upper respiratory tract infection with flu-like symptoms of headache, myalgias, nausea, and vomiting. The severity of the disease can range from an indolent, slowly evolving infection to a fulminating illness causing prostration within a few hours after the onset of symptoms. The classic skin lesions can be petechial, macular, or maculopapular with pale gray vesicular centers. All are a few millimeters in size but may progress to a confluent hemorrhagic rash. They are most commonly localized to the extremities and trunk but may appear on any part of the body. Meningitis presents with the usual symptoms of meningeal irritation —neck soreness, photophobia, headache—whereas, in meningococcemia, meningeal signs are typically absent (16).

FIGURE 170.8 Meningococcemia. Infection with *Neisseria meningitidis.* (From Fleisher GR, Ludwig W, Baskin MN. *Atlas of Pediatric Emergency Medicine.* Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)

Gram stain and culture of scrapings of the skin lesions are positive in only about half of cases. The diagnosis must often rest on clinical findings and is confirmed by positive cultures of blood or cerebrospinal fluid.

One should entertain the diagnosis of meningococcemia in any patient who presents with fever, malaise, and a petechial or maculopapular rash and include it in the differential diagnosis of other bacteremias (e.g., *Haemophilus influenzae, Streptococcus pneumoniae, S. aureus*), subacute bacterial endocarditis, gonococcemia (few distal papular, hemorrhagic lesions), vasculitis (usually distal purpuric lesions), enteroviral exanthems, and RMSF.

The treatment of choice for meningococcemia is high-dose IV antibiotics. Penicillin G (2 million units every 2 hours), ampicillin (2 g every 6 hours), chloramphenicol (4 g/d), and ceftriaxone (up to 4 g/d [100 mg/kg] in children) have all been shown to be effective. Complications such as shock, disseminated intravascular coagulation, adult respiratory distress syndrome, or metabolic acidosis require aggressive supportive care. Prophylaxis is recommended for close school and household contacts. Rifampin, 600 mg (10 mg/kg for children, 5 mg/kg for infants younger than 1 month), is given orally twice daily for 2 days. Single-dose therapy of ciprofloxacin, 500 mg orally, or ceftriaxone, 250 mg IM, are also alternatives for adults.

A related syndrome, chronic meningococcemia, presents as periodic fever, localized rash, myalgia, and arthralgias lasting for several days. The number of skin lesions is small. Episodes may recur over a period of weeks to months. The diagnosis is established by positive cultures (especially of blood) during the febrile episodes. A fair percentage of patients proceed, if untreated, to an acute phase of disease. The differential diagnosis includes subacute bacterial endocarditis, rheumatic fever, gonococcemia, and Henoch–Schönlein purpura.

Treatment is the same as for acute meningococcal disease, except that lower doses of IV antibiotics are generally considered sufficient to eradicate the infection. All patients suspected of having meningococcal disease should be admitted to the hospital for evaluation and treatment, regardless of clinical appearance.

RMSF (see Chapter 186) is an acute infectious disease caused by *Rickettsia rickettsii* and transmitted by the bites of several species of ticks (*Dermacentor andersoni* in the western US, *Dermacentor variabilis* in the eastern US, and *Amblyomma americanum* in some southwestern areas) (Fig. 170.9). RMSF is not limited to the Rocky mountain area; in fact, the areas of highest incidence are in the South Atlantic region and western south-central states. The organisms can be introduced directly into the skin by a tick bite or may enter broken skin with the tick's feces. Once the infection is established, the organisms invade vascular endothelial cells, causing localized thrombosis and necrosis. The disease is manifested clinically by fever, rash, myalgia, and headache. It ranges in severity from a mild, self-limited illness to severe, life-threatening disease (17).

FIGURE 170.9 Rocky mountain spotted fever. (Courtesy of Sidney Sussman, MD.)

RMSF is seen most commonly in the late spring and early summer. The incubation period ranges from 3 to 12 days. There is an abrupt onset of fever, chills, arthralgia, and headache, which is usually severe, with or without nausea, vomiting, and photophobia. The rash appears between the second and sixth days of the illness, beginning peripherally on the wrists, ankles, and forearms as a macular erythematous rash and extending to the palms, soles, and torso. The lesions become maculopapular in a few days in most cases and become petechial shortly thereafter (2 to 4 days after the start of the rash). The rash may be absent in 12% to 17% of cases and may be

difficult to appreciate in dark-skinned individuals (1). Areas of decreased circulation, such as the distal extremities, nose, and ear lobes, may develop areas of infarction; finding such lesions on the scrotum or vaginal area can be an additional clue to the diagnosis.

The differential diagnosis of RMSF includes TSS, meningococcal meningitis, Kawasaki disease, measles, leptospirosis, Colorado tick fever, enteroviral infections, any cause of disseminated intravascular coagulation and vasculitis, mononucleosis, rat-bite fever, atypical measles, and other rickettsial diseases. Among the latter are murine typhus and epidemic typhus, which both have rashes that usually begin on the trunk rather than on the distal extremities.

The treatment of choice for RMSF is doxycycline (100 mg every 12 hours) for 7 to 10 days or tetracycline (25 to 50 mg/kg in divided doses four times daily, not to exceed 2 g/d). Years ago because of concern over dental effects of tetracycline, chloramphenicol (50 to 100 mg/kg/d in four divided doses) was used to treat children, and is currently recommended in pregnancy. Tetracycline usually does not affect enamel formation in the incisors, canines, and bicuspids after age 7 (18,19). Moreover, in children younger than 5 years, it is unlikely to result in any apparent change in tooth color when fewer than five courses of therapy are given in the usual oral dosage (18,19). More recent studies on tooth enamel staining have not shown staining in teeth owing to short courses of doxycycline in children ages 2 to 8 years (18,20) and with an average age of 5 years (18,20). The American Academy of Pediatrics Committee on Infectious Disease revised their recommendations in 1997 and named doxycycline as the antibiotic of choice for treating possible or confirmed RMSF and ehrlichial infections in children, regardless of age. The dose of doxycycline in children weighing <100 lb is 2.2 mg/kg body weight in divided doses twice daily. The adult dose is 100 mg twice daily.

SKIN CANCER

Skin cancers are life-threatening if not diagnosed early. Yet early diagnosis can lead to cure rates in more than 90% of patients in the most common types of skin cancer. Discussion in this chapter focuses

on clinical recognition as described further, illustrated with supplementary photographs. As management is primarily by the dermatologist, definitive diagnostic points and treatment are discussed only briefly.

Basal cell carcinoma (BCC) (Fig. 170.10) is the most common skin cancer. It is usually found in men older than 50 years. Ninety percent are on the sun-exposed head and neck, with the trunk being the next most common site. There are four types. The *noduloulcerative* BCC begins as a small pearly papule that enlarges over the years into a nodule with a waxy edge, a few telangiectatic vessels, and an ulcer on the surface. The *pigmented type* looks the same with the addition of some black or brown pigment. *Sclerosing basal cell cancer,* usually on the face, looks like a whitish scarred patch without any ulceration or telangiectases. *Superficial basal cell cancer* is the most innocuous-looking, resembling a dermatitis. It usually appears on the back and the chest and it looks like a reddish patch with slight scale. The border may have telangiectatic vessels and be slightly raised. The center may be atrophic with superficial ulceration.

FIGURE 170.10 Basal cell carcinoma (BCC). Pearly papule: The tumor exhibits typical rolled pearly borders with telangiectases and central ulceration. (From Elder AD, Elenitsas R, Johnson BL, et al. *Synopsis and Atlas of Lever's Histopathology of the Skin.* Philadelphia,

PA: Lippincott Williams & Wilkins; 1999, p 2, clin. fig. IA1; p 163, clin. fig. IVE3; p 167&#044.)

Squamous cell carcinoma (Fig. 170.11) accounts for 20% of all skin cancer other than melanoma. It occurs most commonly on sun-exposed areas of the face, scalp, lip, ear, and neck and the dorsal hand. Scars from radiation or burns may develop squamous cell carcinoma and are more likely to metastasize. The most common lesion is a quickly growing nodule with an ulcerated center and a firm raised border surrounded by redness. Cure rates are 90%, and metastasis (4% overall) manifests as regional lymphadenopathy.

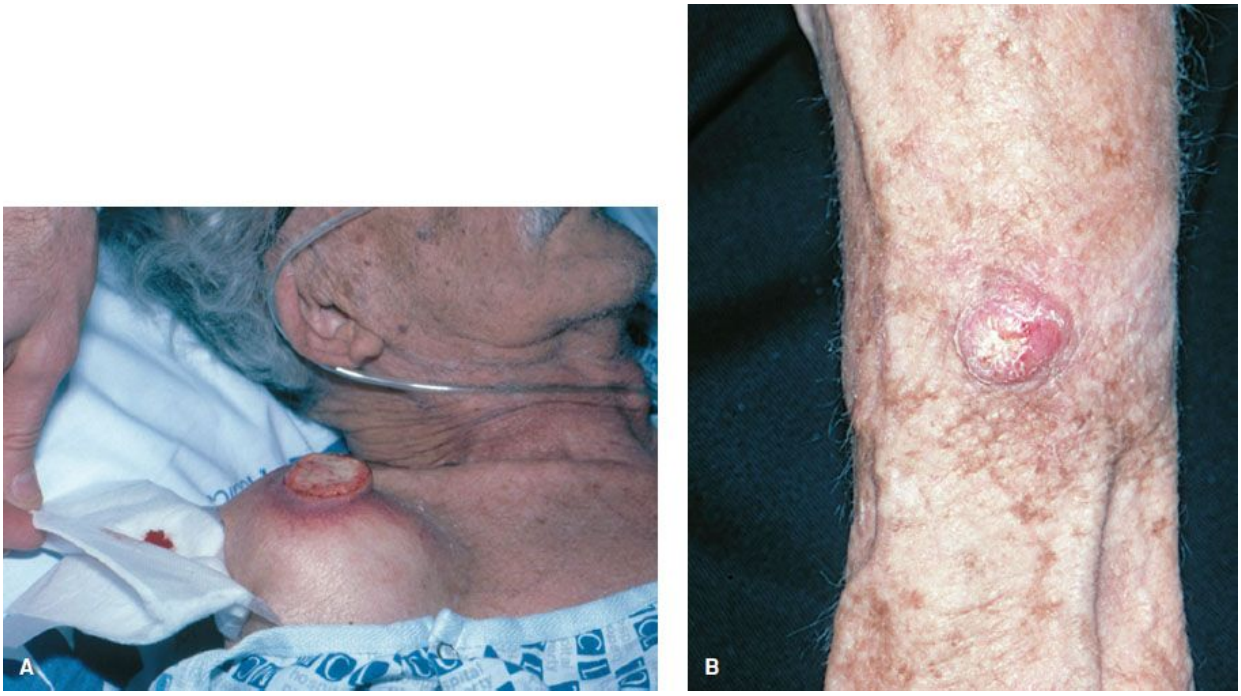

FIGURE 170.11 Squamous cell carcinoma. **A:** This neglected tumor has ulcerated. **B:** This reddish nodule is indistinguishable from BCC. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Malignant melanoma (Fig. 170.12) is a pigmented skin cancer developing on previous nevi or de novo on sun-exposed areas, such as the face and forearms, or on the back of men and the lower legs of

women. Amelanotic melanomas are rare and challenging to diagnose. Although melanomas make up only 1% of the skin cancers in the US, they account for >60% of the deaths. Yet, the most common type, the superficial spreading melanoma, has 5-year survival rates of almost 98% when thin and removed early. It has five cardinal features (5):

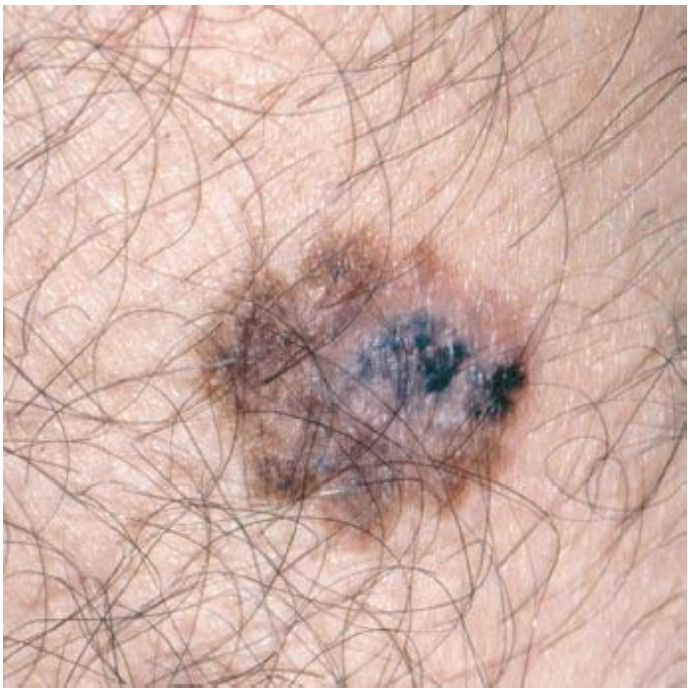

FIGURE 170.12 Malignant melanoma. Note the variegation in color and the irregular, notched border. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

1. **A**symmetry
2. **B**order is irregular
3. **C**olor is mottled, haphazard display of brown, black, gray, and pink (beware of no color in amelanotic melanoma)
4. **D**iameter >6 mm (the size of a pencil eraser)
5. **E**nlargement growth in size; elevation, usually with surface distortion (2)

Changes in a recent or longstanding skin lesion that are suspicious include changes in size, shape, pigmentation, surrounding erythema,

induration, friability, and ulceration (9).

Diagnosis of all the skin cancers relies on early clinical suspicion and referral to a dermatologist for diagnosis by removing the lesion for pathologic diagnosis and staging. Additional chemotherapy or radiotherapy may be indicated for metastasis squamous cell carcinoma or advanced melanoma.

Kaposi sarcoma (Fig. 170.13) is a vascular neoplasm seen in the United States, mostly in patients with AIDS and low CD4 cell counts. With the advent of effective therapy to manage HIV, Kaposi is uncommonly seen now. It can also occur sporadically in elderly men and in Europeans and Africans unrelated to their HIV status.

FIGURE 170.13 Kaposi's sarcoma. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

It appears as red, purple, or brown papules or plaques, solitary or multiple, on skin or mucous membrane. Internal organs may be involved as well, including the gastrointestinal (GI) tract and lungs. Diagnosis is made by clinical appearance in the appropriate individual. Management focuses on controlling the underlying disease.

Cutaneous T-cell lymphoma (mycosis fungoides; Fig. 170.14) is a cancer of CD4 cells. It usually affects people in their forties and fifties, twice as many men as women, twice as many blacks as whites. They report asymptomatic or pruritic patches of abnormal-appearing skin unresponsive to treatment. Occasionally, they may have fever, night sweats, and weight loss. Sezary syndrome is considered to be an erythrodermic, leukemic variant of mycosis fungoides with generalized erythroderma, lymphadenopathy, and atypical T-cells (Sezary cells) in the peripheral blood. Patients with Sézary syndrome have a worse prognosis than those with mycosis fungoides and erythroderma but without lymphadenopathy and atypical T-cells in the blood (6). The diagnosis is made by multiple lesional biopsies over time. Treatment can either be systemic for more advanced disease or related to the skin disease.

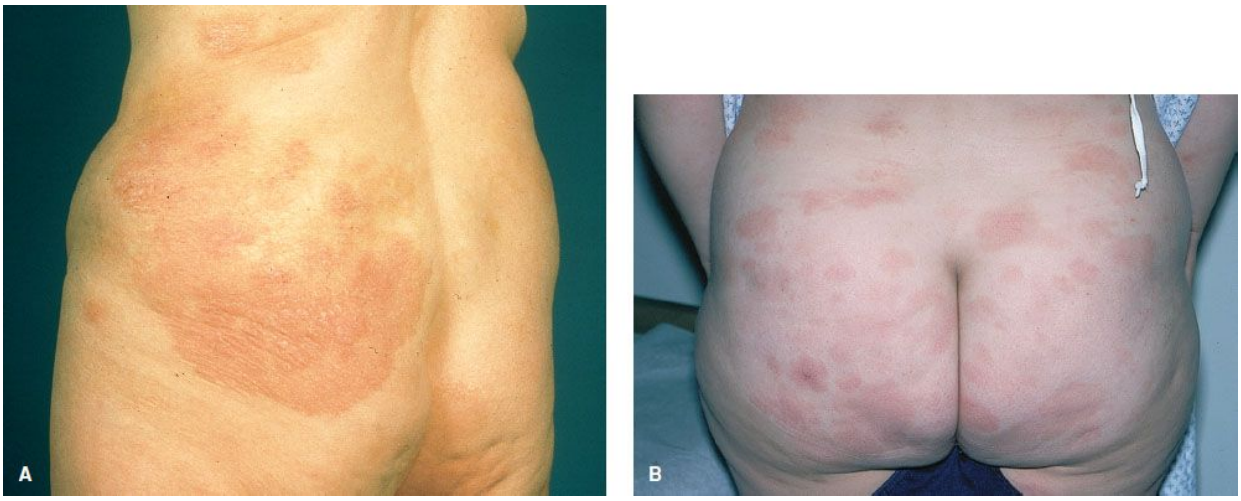

FIGURE 170.14 Mycosis fungoides. **A:** A 66-year-old woman presented with a 30-year history of erythematous scaly patches and plaques with telangiectases, atrophy, and pigmentation. (From Elder AD, Elenitsas R, Johnson BL, et al. *Synopsis and Atlas of Lever's Histopathology of the Skin*. Philadelphia, PA: Lippincott Williams & Wilkins; 1999, p 2, clin. fig. IA1; p 163, clin. fig. IVE3; p 167&#044.) **B:** Lesions have characteristic "smudgy," poorly defined patches and plaques in a typical location. (From Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

CRITICAL INTERVENTIONS

- Search for Nikolsky sign in diffuse red skin rashes.
- Initiate antibiotics for patients with suspected meningococcemia.
- Recognize that most melanomas are pigmented and develop changes in size, shape, and pigmentation.

Common Pitfalls

- TEN can easily be confused with SSSS. TEN requires the removal of any possible precipitating agent, most commonly a drug; SSSS must be treated with appropriate antibiotics. The prognosis of the two diseases is markedly different.
- The rash of TSS may be indistinct. The diagnosis should be considered in any patient with fever and signs of volume depletion, even in the absence of a history of tampon use. The disease can occur in men and children.
- Bullous pemphigoid can easily be confused with pemphigus vulgaris. Early consultation with a dermatologist may be necessary to avoid misdiagnosis and inappropriate treatment.
- In a febrile, seriously ill patient, skin lesions may be a manifestation of sepsis. The lesions should be opened and their contents Gram-stained and cultured.
- Rapid identification and treatment are crucial in ecthyma gangrenosum. The underlying septic process can be fatal if not treated promptly.
- The diagnosis of gonococcemia is often overlooked in persons presenting with tendinitis without any history of injury.
- The early rash of meningococcemia may be macular, maculopapular, or petechial.
- In RMSF, the rash is absent in a significant proportion of cases. An increased index of suspicion is necessary for any patient presenting with a viral-like illness in the late spring or early summer.
- Although BCC is usually waxy and ulcerative, it may also appear to be an innocuous dermatitis.

- Asymptomatic or pruritic patches of abnormal skin which are unresponsive to treatment may represent cutaneous T-cell lymphoma.

CHAPTER 171

Papulosquamous Eruptions

Mark Spektor and John J. Kelly

Papulosquamous lesions are characterized by papules and scaly desquamation of the skin. The lesions may also be macular and erythematous. Diseases in this group include psoriasis, seborrheic dermatitis, pityriasis rosea (PR), lichen planus, and secondary syphilis. Other diseases that may be part of the differential diagnosis include tinea, discoid lupus erythematosus, mixed connective tissue diseases, and scabies. Papulosquamous eruptions are the most common cutaneous manifestations of human immunodeficiency virus (HIV) infection, and their appearance may be the first clue of HIV infection in an otherwise asymptomatic host (19). In addition, a large number of drugs are known to cause papulosquamous eruptions.

When evaluating a papulosquamous eruption in the emergency department (ED), the physician should look for clues to help differentiate the possible etiologies. Is the rash disseminated or localized? Does it appear on specific areas of the body, such as the elbows, knees, scalp, palms, soles, web spaces, or sun-exposed areas? Is it a well marginated, ring-shaped, or isolated lesion (herald patch)? Are the papules pruritic or purple? Answering these basic questions and using the algorithm in Figure 171.1, most papulosquamous diseases are diagnosed without dermatologic consultation.

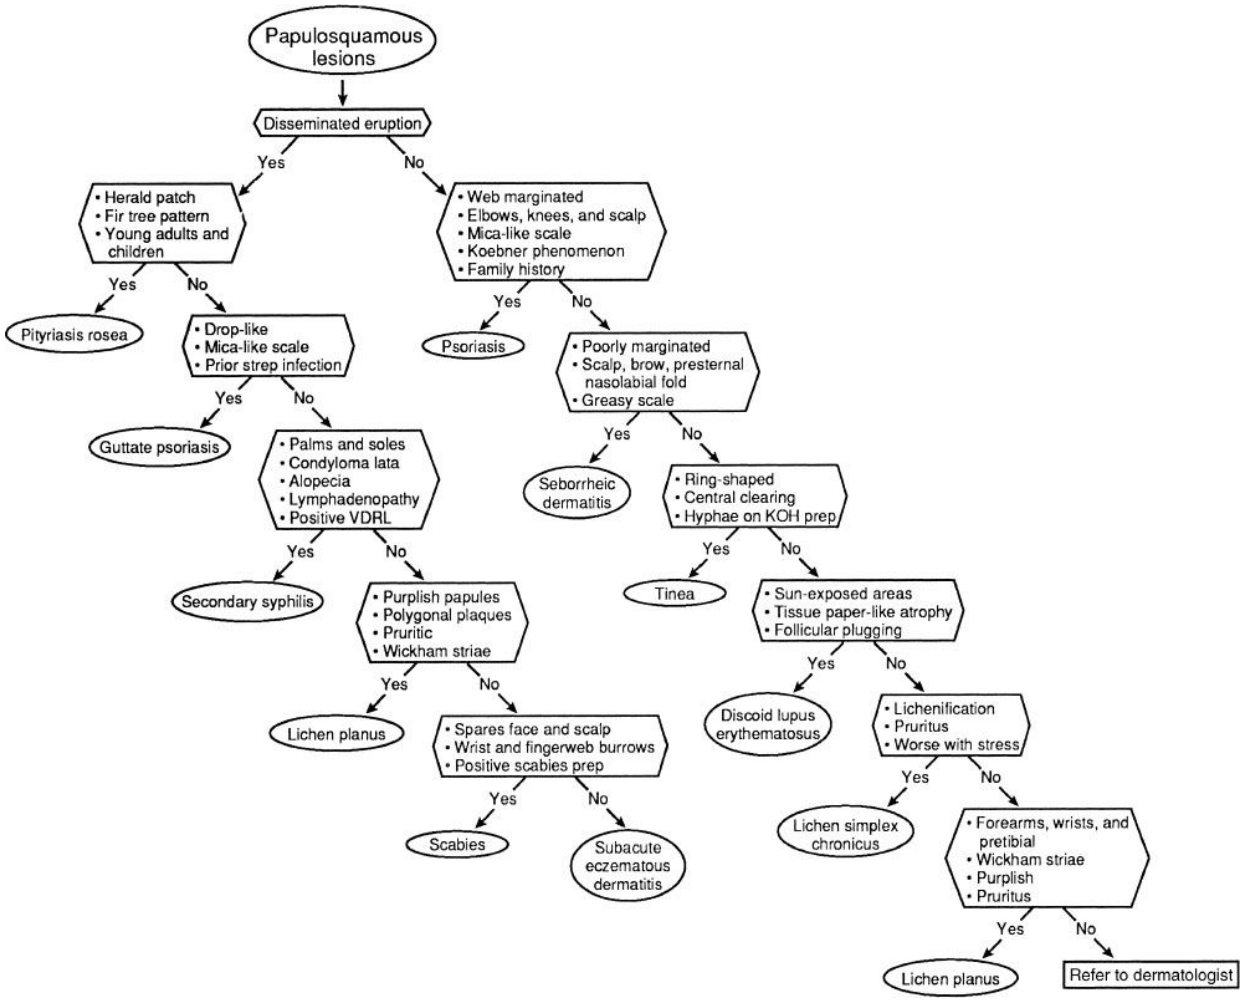

FIGURE 171.1 Algorithm for papulosquamous diseases. (Reproduced with permission from Flowers FP, Krusinski PA. *Dermatology in Ambulatory and Emergency Medicine*. Chicago: Year Book Medical; 1984.)

PSORIASIS

Psoriasis, the most common papulosquamous dermatosis, is found in about 0.6% to 4.8% of the general population (18). The disease is slightly more common in men, and no reliable data exist to support the common assumption that psoriasis is less common in blacks (9,18). Although it is more common during the second and third decades, it may manifest itself at any age and has been reported to be present at birth. The pathogenesis of psoriasis is not completely understood, although there is clearly a genetic component, and

several chromosomal loci have been implicated. T cell-mediated autoimmune mechanisms, such as those involving cytokines, appear to drive development of the plaques, which may begin in response to an environmental factor such as a viral antigen (20). New therapies are focusing on T cell biologic agents.

CLINICAL PRESENTATION

The most common form of psoriasis, plaque psoriasis, occurs in approximately 80% of patients. In this type of disease presentation, lesions are characterized by well-delineated, salmon-colored papules that are soon covered by silvery white scales (Fig. 171.2). They involve both the dermis and epidermis; the depth of involvement depends on their age and location. As the lesions age, the epidermal layer thins, exposing underlying capillary beds. These capillary beds may bleed when the overlying keratotic epidermis is sheared away by mechanical force. This phenomenon, known as the *Auspitz sign,* is diagnostic of psoriasis. Common sites for plaque psoriasis are the scalp, extensor surfaces of the extremities, palms, soles, nails, and the intergluteal cleft. Patients may present with inverse psoriasis in which the lesions affect the flexural sites such as axillae and antecubital and popliteal fossae.

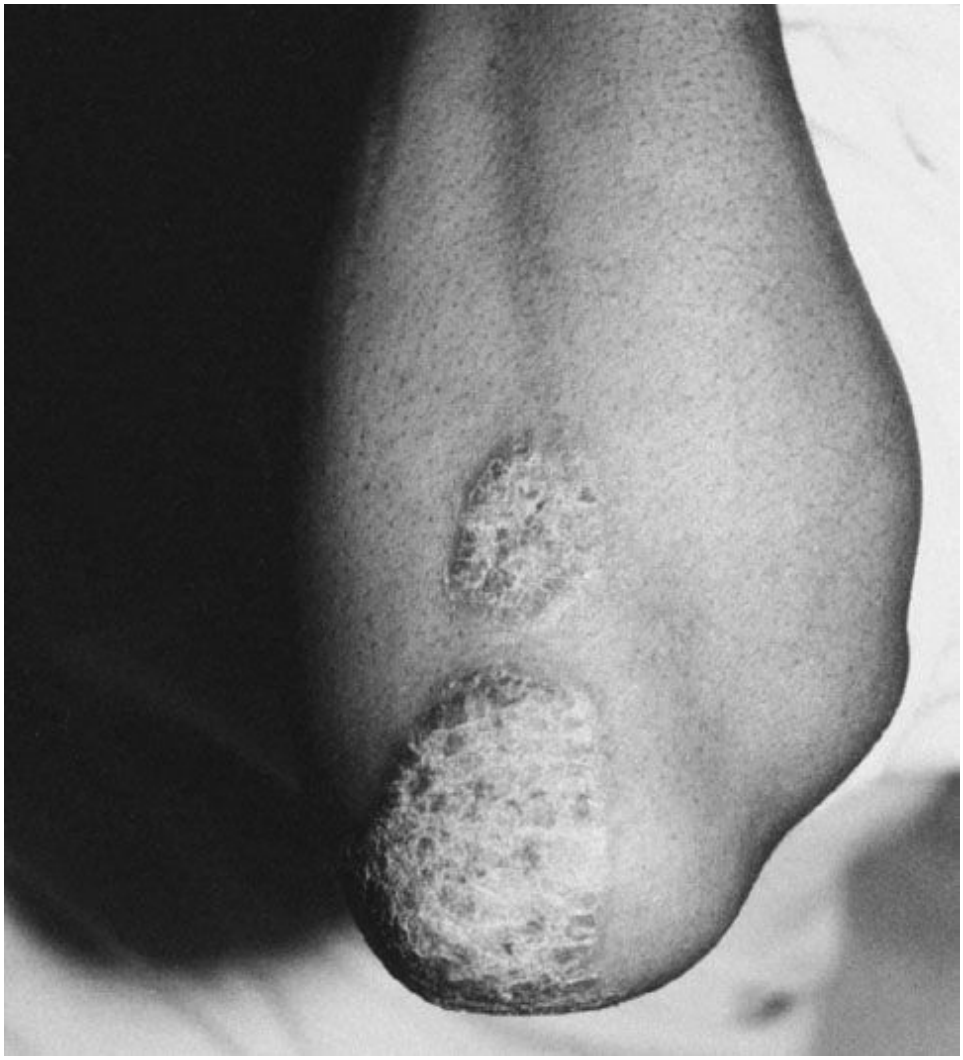

FIGURE 171.2 Well-defined erythematous, scaling plaques on the extensor surface of the arm in a patient with psoriasis.

Between 5% and 42% of patients with psoriasis develop psoriatic arthritis, which is seronegative for rheumatoid factor. The arthritis is typically asymmetric and involves fingers and toes. Cutaneous lesions precede joint disease in 60% to 70% of the cases but may present simultaneously. In 20% of patients, the onset of arthritis is prior to the skin changes (2).

Nail abnormalities are eventually seen in most patients. The nails are commonly pitted and show a brownish or whitish discoloration and an accumulation of scale on the nail bed. Nail changes may precede skin finding in up to 4% of patients (Fig. 171.3) (20).

FIGURE 171.3 Psoriasis of the nails.

Pustular psoriasis is characterized by erythematous areas covered with sterile pustules. It may be localized or general and may affect the hands and feet in addition to the trunk and extremities. In extreme cases, pustules become confluent, forming large lakes of pus. Generalized pustular psoriasis has an acute onset associated with malaise, pyrexia, and leukocytosis, and it is potentially fatal if untreated. Factors known to induce generalized pustular psoriasis include a tapering of the dose of systemic corticosteroids, withdrawal of potent topical steroids, nonsteroidal anti-inflammatory agents, pregnancy, viral upper respiratory tract infections, and beta-hemolytic streptococcal infections (7).

Guttate psoriasis usually follows streptococcal infections. It is characterized by sudden appearance of lesions on the trunk and extremities.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of psoriasis includes tinea cruris, candidiasis, secondary syphilis, PR, cutaneous lupus erythematosus, and seborrheic dermatitis (6), and intertrigo when the eruption

occurs in the intertriginous areas. Seborrheic dermatitis may resemble psoriasis of the scalp but usually has finer and more widespread yellow scaling. A helpful clue in differentiating psoriasis from other conditions is the presence of psoriatic nail changes: pitting of the nails and separation of the nail from the underlying nail bed (6). Guttate psoriasis on the trunk is easily confused with PR.

ED EVALUATION

After a thorough history for chronic recurrent rash, inspect the entire skin, especially the scalp, extensor surfaces of the extremities, palms, soles, nails, and the intergluteal cleft. If the diagnosis is unclear based on history and physical examination, laboratory investigation based on clinical findings, including a rapid plasma reagin (RPR) to exclude syphilis, is appropriate.

ED MANAGEMENT

Mild psoriasis is usually treated with topical preparations and phototherapy. More severe or widespread cases may require systemic treatment. Topical therapy includes emollients, corticosteroids, tars, anthralin, salicylic acid, tazarotene, and vitamin D analogues. The use of tars has been described since 1925 (8) but has fallen out of favor owing to limited effectiveness and staining. Coal tar and salicylic acid shampoos are still widely used in psoriasis of the scalp (21).

Topical corticosteroids are the most prescribed medications for psoriasis treatment. Corticosteroids are highly and rapidly effective; however, side effects such as cutaneous atrophy, striae, and formation of telangiectasia have limited their long-term utility. Vitamin D analogues such as calcipotriol, calcitriol, and tacalcitol have emerged as an alternative to corticosteroids. These agents exert their effect through inhibition of epidermal proliferation, enhancement of cornification, and inhibition of inflammation (21). Although they lack the side effect profile of corticosteroids, vitamin D analogues have a somewhat limited effectiveness (15). Topical retinoids such as tazarotene have been utilized for treatment of

psoriasis. They have been shown to be as effective as mid- and high-potency steroids. Local irritation is a common side effect (13). Topical immunosuppressants such as tacrolimus and pimecrolimus have recently gained acceptance. More severe cases of psoriasis may require systemic treatment or phototherapy. Systemic therapy includes methotrexate, cyclosporin, systemic steroids, systemic retinoids, and most recently the biologics. This class of drugs includes etanercept, infliximab (21), adalimumab, and ustekinumab. Initiation of systemic medication and phototherapy should be made under the direction of a dermatologist.

DISPOSITION

Psoriasis is rarely dangerous or life threatening and is usually best cared for by a dermatologist who can follow up the patient over time. Topical steroids or coal tar may be initiated in the ED, but treatment with ultraviolet A (UVA) or systemic therapy should be performed under the direction of a dermatologist, usually in the hospital. The patient who appears toxic should be admitted for intravenous antibiotics.

Common Pitfalls

- Psoriasis of the trunk and extremities is rarely confused with other diseases, but in the intertriginous areas, it may be confused with tinea cruris, candidiasis, or intertrigo. Close examination with a Wood's light and potassium hydroxide (KOH) preparation should help differentiate these diseases. Some patients may have both diseases.
- If steroids are used to treat psoriasis, systemic steroids should be avoided. They are very effective but can cause long-term side effects, and the disease often rebounds when steroids are stopped.
- New cases of psoriasis, sudden, severe exacerbations, or cases refractory to treatment should alert the clinician to the possibility of HIV infection.

PITYRIASIS ROSEA

PR is an acute, self-limited, inflammatory dermatosis seen most commonly in children and adolescents. PR has been reported in all ages, but approximately 50% of cases occur before the age of 20 years. It affects both genders equally and has an increased incidence in spring and fall (11). The etiology is uncertain, but an association with viral infection such as human herpesvirus 6 and 7 has been suggested, with little data to support the idea (5). In addition, many drugs have been reported to cause PR-like reactions (Table 171.1).

TABLE 171.1
Drugs Associated with Pityriasis Rosea–Like Eruption

Ketotifen
Captopril
Isotretinoin
Metronidazole
D-penicillamine
Levamisole
Gold
Bismuth
Arsenic
Barbiturates
Clonidine

CLINICAL PRESENTATION

PR is characterized by oval, salmon-colored, pruritic, scaling patches on the neck and trunk that follow Langer lines (skin cleavage lines) (Fig. 171.4). On the back, this produces a so called Christmas tree pattern. The rash may be found on the palms and soles, and it may involve the oral mucosa and gingiva. Characteristically, this generalized eruption is preceded by a 2- to 5-cm herald patch, but it is absent in up to 50% of patients. Within 7 to 14 days, other lesions appear, which, in young children, may involve the face, scalp, and distal extremities. Oral lesions may be present in up to 16% of patients (22). An atypical presentation (inverse PR) spares the trunk, affecting only the face and extremities. Papular form of PR has also

been described (1). The rash usually lasts 4 to 7 weeks but may last up to 5 months.

FIGURE 171.4 Circular and ovoid papules and plaques with scaling on the trunk and proximal extremities in a patient with pityriasis rosea.

The most common complaints associated with PR are pruritus and mild constitutional symptoms such as malaise, fever, and lymphadenopathy. It poses no risk to the fetus if it occurs in pregnant women and it does not appear to be contagious.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes tinea corporis when there are a few lesions and secondary lues when there are many (although luetic lesions tend to be less pruritic). The herald patch is commonly misdiagnosed as ringworm. A KOH preparation of scrapings from the lesions is negative, however. Examination of tinea corporis with a Wood's light produces a bright green fluorescence, but no fluorescence is seen with PR. Guttate psoriasis, which is distributed mainly on the trunk, has thicker, more silvery scales than does PR. Lichen planus may have a similar appearance, but the lesions are

purple, not salmon colored. Eruptions resembling PR may also be caused by numerous medications (Table 171.1). Because the skin eruption of secondary syphilis may mimic that of pityriasis, a venereal disease research laboratory (VDRL) or RPR should be drawn.

ED EVALUATION

Conduct a thorough history and skin examination, looking for classic features such as the herald patch and Christmas-tree distribution. Obtain an RPR to exclude syphilis if the diagnosis is unclear.

ED MANAGEMENT AND DISPOSITION

Pityriasis is a benign, self-limited disease that does not require therapy. Symptomatic treatment for pruritus may include emollients, antihistamines, and intermediate-strength topical steroids. Treatment with erythromycin has been shown to be effective (17), but the mechanism of action remains unclear. One current hypothesis suggests that erythromycin may provide an anti-inflammatory and immunomodulatory effect (3). UVA may accelerate resolution of the lesions.

If the diagnosis is made with certainty, consultation with a dermatologist is unnecessary. The patient may be discharged to follow up with the family physician. If the diagnosis is in question, the patient should be referred to a dermatologist. If the rash lasts more than 3 months, the physician should be prompted to reconsider the original diagnosis.

Common Pitfalls

- PR is often misdiagnosed. The herald patch can resemble tinea corporis and may be incorrectly treated with antifungal medication until the generalized rash appears.
- Later, the generalized rash may be mistaken for lichen planus or a drug eruption. A careful history and physical examination decrease the likelihood of these errors.

- The wise clinician draws an RPR test or VDRL test to rule out "the great masquerader."

LICHEN PLANUS

Lichen planus is a relatively uncommon inflammatory dermatitis characterized by violaceous, flat-topped papules. The disease is most common between ages 30 and 60 and is seen with approximately equal frequency in men and women. Viral and bacterial agents and genetic predisposition and immunologic factors have been suggested as causes. In addition, several drugs have been implicated in causing a lichen planus–like eruption (Table 171.2).

TABLE 171.2
Drugs Causing Lichenoid Drug Reactions

Beta blockers	Captopril
Methyldopa	Thiazides
Furosemide	Gold
Antimalarials	Quinidine
Oral hypoglycemic agents	Phenytoin
Carbamazepine	Antituberculous agents
Antihistamines	Phenylbutazone
Antipsychotics	Bismuth
p-Aminosalicylic acid	Lithium

CLINICAL PRESENTATION

The lesions of lichen planus may be described using the six Ps: pruritic, polygonal, planar, purple papules, and plaques. Most appear to be slightly scaly with a fine reticular pattern of white dots and lines on their surface (Fig. 171.5). They are commonly found on the wrist, volar surface of the forearms, and pretibial areas, but may also appear on the scalp, palms, soles, lips, and genital mucosa. On the palms and soles, they are commonly yellowish and nonpruritic. The lesions commonly develop at sites of trauma (Koebner phenomenon). For this reason, they are often found in a linear pattern, presumably owing to scratching. More than one-half of patients with cutaneous

lichen planus have oral mucosal lesions as well. These are whitish plaques with a lacy, whitish, reticular pattern (Wickham striae) (Fig. 171.6). Patients may present with oral lesions alone.

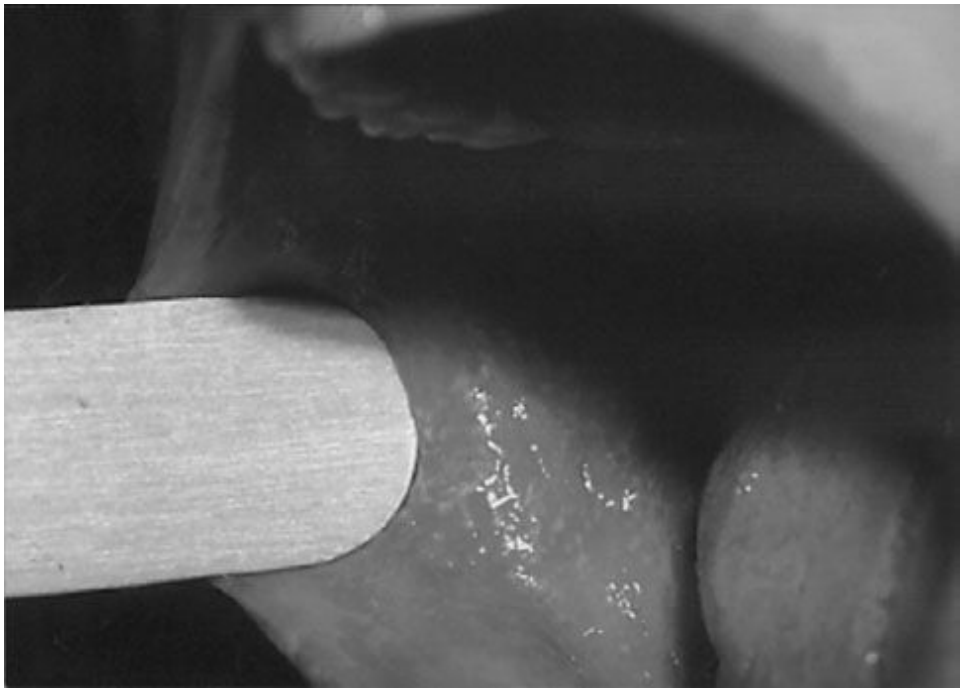

FIGURE 171.6 Oral lesions of lichen planus.

FIGURE 171.5 Gray to violaceous flat-topped papules on the flexural surface of the forearm in a patient with lichen planus.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of lichen planus includes psoriasis, fungal infection, secondary syphilis, PR, and discoid lupus erythematosus. When the mucous membranes are involved, leukoplakia and candidiasis are considerations.

ED EVALUATION

Perform a thorough examination of the skin, palms, soles, and oral mucosa. Order an RPR to exclude syphilis if the diagnosis is uncertain.

ED MANAGEMENT AND DISPOSITION

Lichen planus is a self-limited disease that may last for weeks to years. Most patients experience a spontaneous resolution within a year. Several cases of squamous cell carcinoma have been reported in association with oral lichen planus (12). Therefore, proper follow-up arrangements are required. Treatment includes antihistamines for pruritus and topical steroids for inflammatory lesions. Occasionally, with widespread lesions, systemic steroids may be used. In cases that are resistant to corticosteroids, retinoids such as acitretin may be considered (4). Biologics such as efalizumab have also been shown to be effective (3). Patients with lichen planus should be referred to a dermatologist for long-term follow-up, although treatment with topical agents and antihistamines may be initiated in the ED.

Common Pitfalls

- Lichen planus frequently involves the oral mucosa; in fact, 15% to 25% of patients with oral lichen planus never develop skin lesions. It is also one of the few rashes that may affect the palms and soles. A close physical examination, not only of the obvious lesions on the arms and trunk but of the mouth, palms, and soles, is important in making the correct diagnosis.
- In light of the recently described association between lichen planus and the hepatitis C virus (HCV), patients should be referred for prompt evaluation for HCV infection (16).

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a chronic, superficial, inflammatory process affecting regions of the body with increased sebaceous gland activity. It is more common in males and occurs in infants younger than 12 months, among adolescents, and in elderly persons. It is more severe in winter. It is particularly common in patients with HIV infection. The etiology is unclear, but it may be caused by dysfunctional sebaceous gland activity owing to hormonal activity (23) or a reaction to the common skin yeasts *Malassezia ovalis* and *Pityrosporum ovale*.

CLINICAL PRESENTATION

The lesions of "oily" seborrheic dermatitis are characterized by poorly defined margins, mild erythema, and greasy yellow scales (Fig. 171.7). "Dry" seborrheic dermatitis exhibits small, dry, powdery scales and little or no erythema. Secondary lesions due to scratching may be seen around the primary lesions. Areas commonly affected include the scalp, face (especially the eyebrows and nasolabial folds), axilla, groin, buttocks, and inframammary folds. In infants, the scalp is frequently affected and is known as *cradle cap*. When the scalp is affected in adults, it is called *dandruff*.

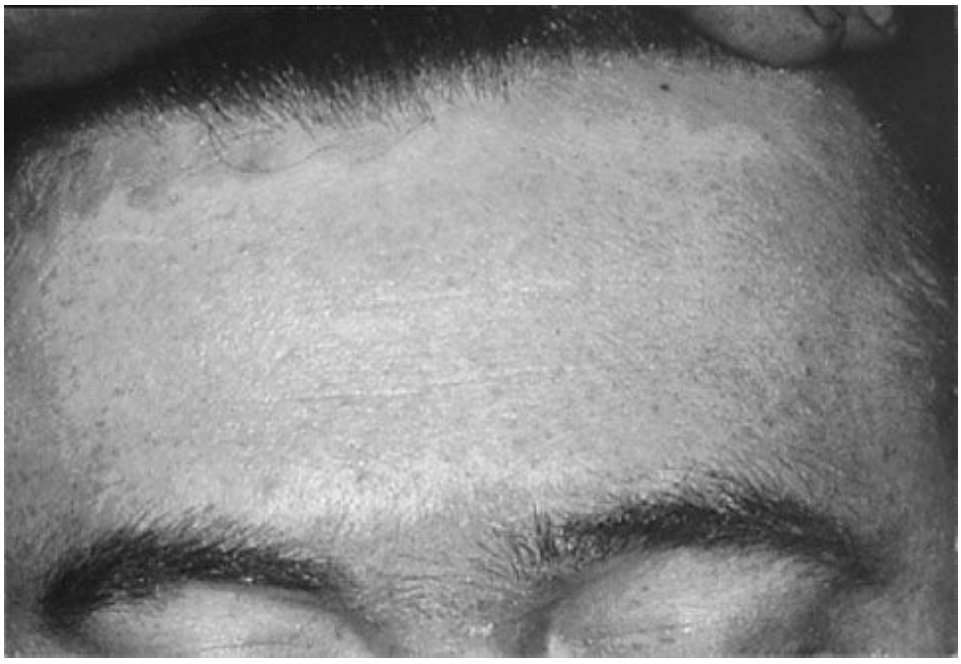

FIGURE 171.7 "Oily" seborrheic dermatitis along scalp hairline and eyebrows.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes psoriasis, tinea, and atopic dermatitis in children. Lesions affecting the scalp, axilla, and groin may be difficult to differentiate from psoriasis. Involvement of the knees, elbows, and nails favors psoriasis. Persistent pruritic lesions that do not respond to therapy may be tinea. In infants, seborrheic dermatitis is commonly seen on the scalp, axilla, and diaper area. Lesions on the forearms and shins favor atopic dermatitis.

ED EVALUATION

Conduct an examination focusing on the scalp, face, axilla, groin, buttocks, and inframammary folds.

Order an RPR if the diagnosis is uncertain.

ED MANAGEMENT AND DISPOSITION

Encouragement of good hygiene is vital in the treatment of seborrhea. Frequent cleansing with soap removes oils from affected areas and therefore decreases the symptoms. Antiseborrheic shampoos containing sulfur, salicylic acid, coal tar, or selenium sulfide provide adequate therapy for most patients. They should be used daily and rubbed into the scalp, with a 5- to 10-minute wait before rinsing. Topical antifungals such as ketoconazole 2% cream and ketoconazole or ciclopirox shampoos have shown good efficacy (10). Topical steroids may be used in areas with dense scale; however, one must be aware of side effects such as atrophy and telangiectasia. Patients with seborrheic dermatitis may be treated on an outpatient basis by the emergency physician and then referred to a dermatologist or the patient's family physician.

Common Pitfalls

- Seborrheic dermatitis is often misdiagnosed. It occurs in infancy as cradle cap and usually does not appear again until puberty. It

is associated with an oily complexion and is often precipitated by fatigue or stress.
- Possibility of HIV infection should be considered.

SECONDARY SYPHILIS

Syphilis (see Chapter 184, "Sexually Transmitted Diseases") is a sexually transmitted infectious disease caused by *Treponema pallidum.* The rash of secondary syphilis appears 9 to 90 days after the onset of the chancre; the average is 3 weeks. Most individuals contract the disease from sexual activity with a person in the early stages of syphilis. The risk of transmission ranges from 9% to 63%, and incidence has been reported at a rate of 3.2 cases per 100,000 persons (18).

CLINICAL PRESENTATION

The rash of secondary syphilis is generalized, painless, and nonpruritic. A primary chancre may be present in as many as one-third of patients with secondary syphilis. As many as 60% of patients do not report recall having a chancre (18). The rash involves the skin and the mucous membranes in 30% to 50% of the cases. On the skin, it tends to follow the lines of cleavage, especially on the trunk. It has a special predilection for the palms and soles (Fig. 171.8). The lesions are scaling, "raw ham," or copper-colored papules and plaques that are discrete and sharply demarcated rather than confluent (Fig. 171.9). Annular plaques on the mouth, nose, and lip areas are virtually diagnostic. The patient's presenting complaint may be an apparently unrelated other symptom, such as headache, sore throat, malaise, and generalized arthralgia.

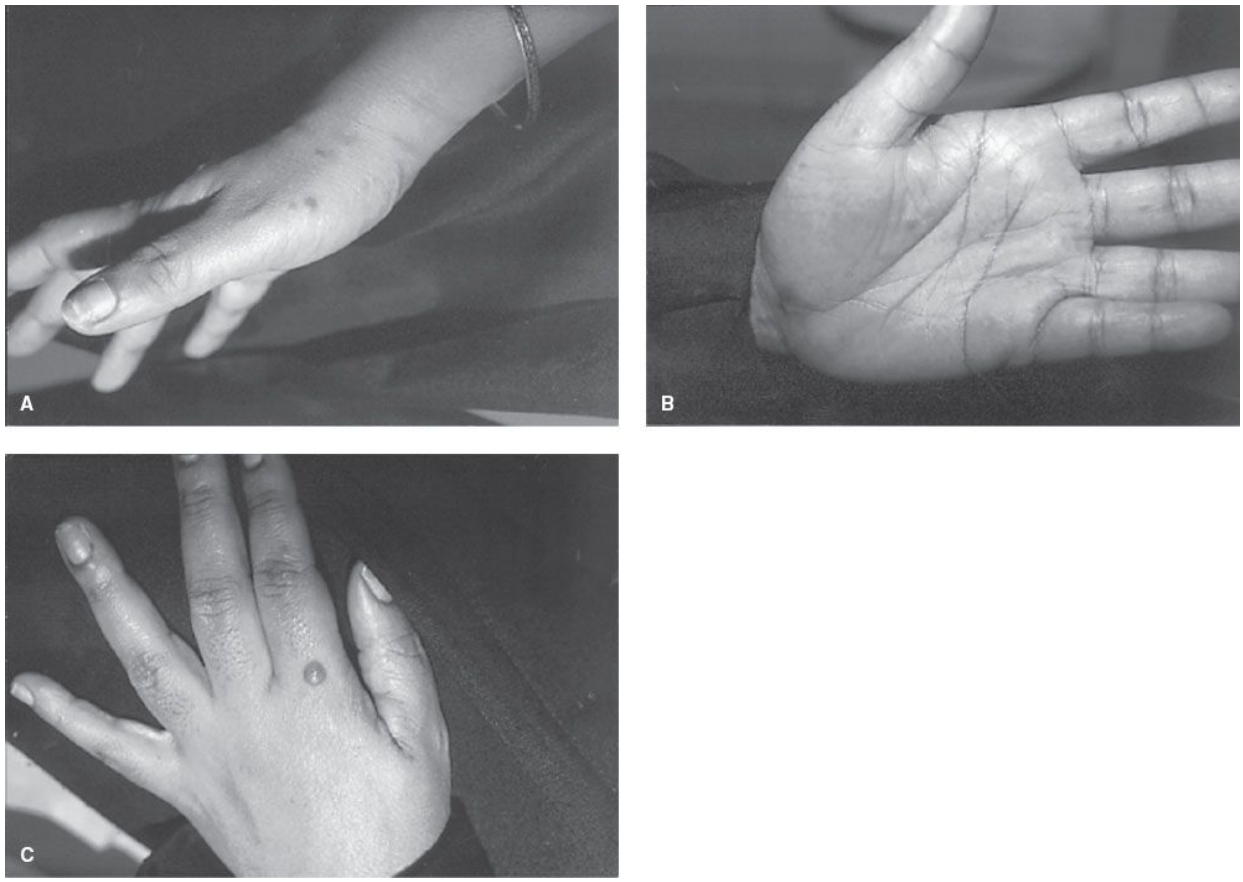

FIGURE 171.8 A–C: Secondary syphilis.

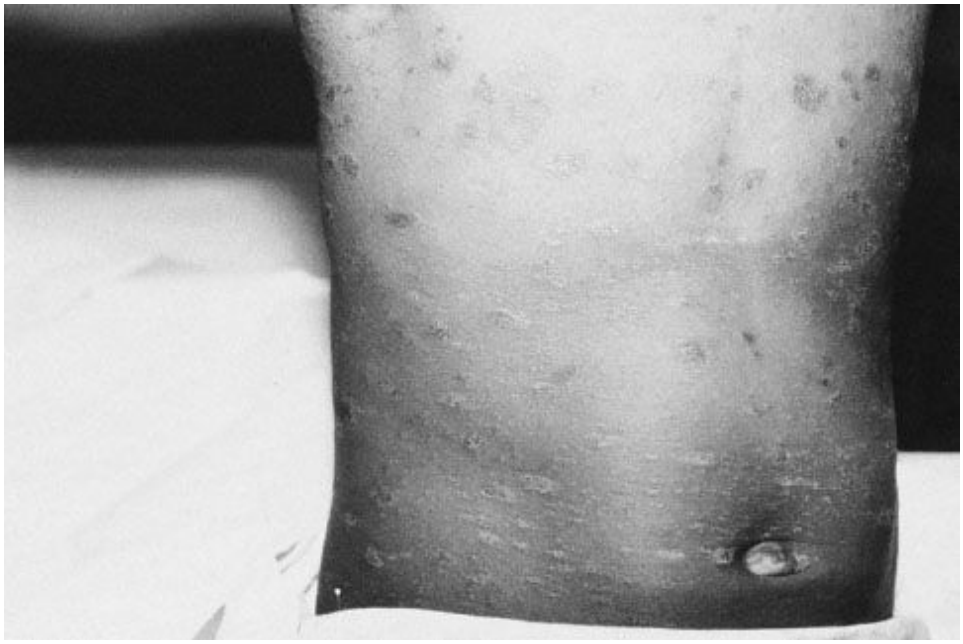

FIGURE 171.9 Diffuse erythematous papules and plaques with scaling in a patient with the rash of secondary syphilis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of secondary syphilis includes PR, Rocky Mountain spotted fever, meningococcemia, drug reaction, and lichen planus. Palmar lesions that mimic secondary syphilis may be secondary to drug eruption.

ED EVALUATION

The examination should include a search for chancre, for mucous membrane lesions, and for annular lesions of the mouth nose or lip. Order an RPR.

ED MANAGEMENT AND DISPOSITION

Diagnostic studies such as VDRL or RPR should be ordered. Dark-field examination of scrapings from lesions may also be performed. If either test is positive, the patient is treated in the ED with either benzathine penicillin G (2.4 million units IM) or aqueous procaine penicillin G (600,000 units IM daily for 8 days). Patients allergic to penicillin may be treated with tetracycline or erythromycin for 10 days.

If the diagnosis of secondary syphilis cannot be made in the ED, the patient should be referred to a private physician or clinic pending the results of VDRL or RPR testing. Hospital admission is unnecessary for secondary syphilis, but the patient should be instructed to abstain from sexual contact until the diagnosis is clear and any necessary treatment has been administered and to refer all sexual partners to testing and treatment, as indicated.

CRITICAL INTERVENTIONS

- Order an RPR in patients with papulosquamous lesions of unclear etiology.

Common Pitfalls

- Failing to elicit a history of a primary lesion preceding the rash. This history and an adequate sexual history are helpful in the initial diagnosis.
- Failing to appreciate the typical erythematous, hyperpigmented, and scaly papules on the palms and soles may lead to an inappropriate diagnosis.
- Because of the strong association of HIV and syphilis, patients newly diagnosed with syphilis should be referred for HIV testing.

CHAPTER 172 Blistering Disorders

Lisa R. Palivos

Vesicular lesions are commonly seen in the emergency department. Like other dermatologic lesions, vesicles can present a challenge in determining their etiology, contagiousness, and proper treatment (1–4).

Vesicles are circumscribed epidermal elevations 1 to 4 mm in diameter that usually contain clear fluid. Several characteristics help distinguish the lesion from other vesicular disorders, including the nature of the contained fluid (seropurulent, serosanguineous), the shape of the lesion's apex (rounded, acuminate, umbilicated), the pattern of the eruption (discrete, irregularly scattered, grouped, linear), and the distribution over the body and associated mucous membrane involvement.

In this discussion, there are two types of vesicular disorders: those appearing in groups and those that are individual or disseminated.

GROUPED LESIONS

Herpes Simplex

Herpes simplex infections are caused by two different DNA virus types: HSV-1 and HSV-2. Both viruses can infect oral or genital mucosa and are spread by direct contact. HSV-1 usually affects the lips and is often referred to as a fever blister or cold sore. HSV-2 is the virus most frequently associated with genital herpes. The hallmark of herpes simplex virus (HSV) infections is the ability to infect epithelial cells and then travel up the peripheral nerve to the

dorsal root ganglia where it may remain latent for years followed by reactivation.

CLINICAL PRESENTATION

Herpes simplex is characterized by recurrent, painful, vesicular lesions of the lips, genitalia, hands, rectum, or eyes. The lesions of herpes simplex are typically tightly clustered vesicles on an erythematous base and evolve into pustules and erosions over 5 to 7 days. Grouped, crusted erosions are the typical presentation. Associated symptoms may include fever, local pain, regional lymphadenopathy, fatigue, and malaise. Urinary retention occasionally occurs with genital lesions and generally requires hospital admission.

Primary lesions are usually more widespread with a bilateral distribution. Recurrent lesions typically are tightly clustered and unilateral and occur in the same location as previous episodes of infection. Recurrences are usually milder, involve fewer lesions, and heal faster. Approximately 50% of patients with recurrent lesions have a 24-hour prodrome of local itching, burning, tingling, and stinging. Precipitating factors for recurrence include stress, fever, infections, sunburn, menstruation, cosmetic facial procedures, dental interventions, or trauma.

Primary lesions usually resolve in 2 to 3 weeks, but the duration may be longer in immunocompromised patients. Typical sites of involvement are the oral, genital, and periorbital areas and the fingertips (herpetic whitlow), but any body area may be involved. Oral infections can cause gingivostomatitis, or pharyngitis. Herpetic whitlow is an infection of the pulp and lateral aspect of the finger. This may occur from autoinoculation with a primary oral or genital infection. With periorbital lesions, fluorescein staining of the cornea is necessary to identify dendritic lesions. Herpetic keratitis is the most common cause of corneal blindness and presents with pain, photophobia, and blurry vision. Patients with herpetic keratitis should be referred to an ophthalmologist. Herpes gladiatorum is contracted by athletes, especially wrestlers. It is transmitted by direct skin-to-skin contact and usually appears in the head and neck region.

With the increasing incidence of the acquired immunodeficiency syndrome and the growing use of bone marrow and solid organ transplantation, more severe manifestations of herpes infections are being seen (5). Neonatal herpes occurs when the virus is transmitted from an infected mother to the neonate, with the highest risk occurring when the mother has primary genital herpes during delivery. Along with the cutaneous lesions, the infected neonate may develop multiorgan involvement with high mortality rate. HSV vaccines are currently in early clinical trials.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of herpes simplex includes aphthous stomatitis; tinea cruris; hand, foot, and mouth disease; herpangina; and primary syphilis. Aphthous stomatitis consists of one or two painful lesions in the mouth, but they are not in a circumscribed area. Although early tinea, which is vesicular, can be difficult to distinguish from herpes, later tinea has central healing. Lesions in hand, foot, and mouth disease are asymptomatic. Herpangina lesions are found in the posterior oropharynx and not outside the mouth. The chancre in primary syphilis is classically painless and the borders are indurated.

ED EVALUATION

Diagnosis of herpes simplex is usually made clinically. Viral cultures of vesicular fluid or direct fluorescent antibody stain of scraped lesions may be helpful for definitive diagnosis. The presence of intranuclear inclusions and multinucleated giant cells on a Tzanck preparation supports a diagnosis of herpes infection but does not distinguish between HSV and varicella zoster virus. Polymerase chain reaction and serology testing are not widely available and are expensive. Point-of-care HSV-2 and HSV-2-LFIA rapid test kits are available. The 10-minute tests only require a few drops of blood from a finger stick to detect the presence of HSV-2 antibodies to confirm genital herpes diagnosis and also identify asymptomatic carriers. They do not detect HSV-1.

ED MANAGEMENT AND DISPOSITION

Acyclovir is the most widely used antiviral agent in clinical use. Treatment with 200 mg of oral acyclovir five times per day or 400 mg three times a day for 10 days is indicated for primary genital herpes. However, the duration of symptoms is decreased only minimally with this therapy and only if started within 24 hours after onset of the rash. Time for crusting decreases from 2.7 to 2.2 days. Other medications that are effective and available for treating herpetic infections are famciclovir and valacyclovir (Table 172.1). All three oral agents have been shown to reduce the frequency of symptomatic recurrences of genital herpes. Over-the-counter tetracaine cream (Viractin) may reduce healing time of recurrent herpes labialis by about 2 days. Topical penciclovir 1% cream (Denavir), which is more effective than acyclovir cream, can reduce average time to healing of recurrent orolabial HSV infections by 0.7 days and the duration of pain by 0.6 days (6).

TABLE 172.1
Treatment of Genital Herpes Simplex

Treatment of Genital Herpes Simplex	Primary Infection	Recurrent Lesions	Suppressive Therapy
Acyclovir	200 mg × 5 d OR 400 mg tid for 10 d	400 mg tid OR 800 mg bid for 5 d	400 mg bid for 12 mos
Famciclovir[a]	250 mg tid for 10 d	125 mg bid for 5 d	250 mg bid for 12 mos
Valacyclovir[a]	1 g bid for 10 d	500 mg bid for 3 d	1 g qd for 6–12 mos

[a]Reduction in dosage is recommended in patients with reduced renal function. Valacyclovir should not be prescribed in patients with HIV or transplant recipients because of the observation of TTP and hemolytic uremic syndrome. Famciclovir is contraindicated with Denavir.

In children with oralfacial or gingivostomatitis, generally, only supportive treatment with hydration and topical anesthetics (viscous lidocaine, diphenhydramine elixir) is needed. Importantly, patients receiving suppressive antiviral medication should be counseled that they may still transmit HSV to their sexual partners. Intravenous therapy (5 mg/kg every 8 hours) should be considered for patients with urinary retention, compromised immunity, or life-threatening disseminated infection.

Common Pitfalls

- Failure to instruct patients about measures to prevent transmission to others.
- Failure to admit patients with genital herpes and urinary retention.
- Failure to admit patients with disseminated infection.
- Failure to recognize herpetic whitlow and making an incision, which may lead to spread of infection.

HERPES ZOSTER

Herpes zoster (HZ) (shingles) results from the reactivation of a dormant varicella zoster virus that entered the dorsal root ganglia during an earlier episode of chicken pox. HZ can occur in patients of any age who have had a previous infection of varicella zoster virus. The incidence of HZ increases with age, peaking in the seventh decade. Reactivation factors include fever, wind, UV light, illness, or stress. An attack of HZ does not confer immunity, and it is not unusual to have two or three episodes in a lifetime.

CLINICAL PRESENTATION

HZ is characterized by unilateral vesicular eruption along one or two adjacent dermatomes that is associated with severe pain. Dermatomes T3–L3 are most frequently involved (Fig. 172.1). Occasionally, the lesions may extend beyond the midline. There is usually a prodrome of pain, itching, burning, and hyperesthesia in the same dermatome 4 to 7 days before the lesions appear. Fever, headache, and malaise along with lymphadenopathy may also precede the eruption. The pain may imitate myocardial infarction, appendicitis, renal colic, or migraine headache and may present a diagnostic dilemma until the characteristic rash develops. The eruption begins as an erythematous maculopapular rash that gives rise to vesicles containing purulent fluid. These pustules either umbilicate or rupture before forming crusts. The crusts fall off in 2 to 3 weeks.

FIGURE 172.1 Herpes zoster. Lesions can involve more than one dermatome. (Courtesy of Scott Sherman, MD.)

When the ophthalmic division of the trigeminal nerve is involved, HZ ophthalmicus results. Lesions can appear on the forehead, eyelid, and nose. Symptoms include headache, fever, malaise, and eye pain. Ocular involvement is common and each individual should have a thorough eye examination. Hutchinson sign (lesion at the tip of the nose) usually heralds ocular involvement. Urgent (next-day) ophthalmology referral is indicated. When the sensory branch of the facial nerve is involved, HZ oticus results. Lesions appear in the ear, mouth, face, neck, or scalp. Patients can complain of severe otalgia, vertigo, hearing loss, or loss of taste in the anterior two-thirds of the tongue. When associated with facial paralysis, the disease is called *Ramsay Hunt syndrome.* Treatment consists of acyclovir, corticosteroids, and diazepam for vertigo. Facial paralysis and hearing loss may be permanent. Patients should be referred to an ear, nose, and throat specialist urgently. Hospitalization should be considered in severe cases.

The severe pain associated with HZ is the principal reason that patients seek medical care. Traditionally, pain that is present while the rash persists or in the first 30 days from onset has been termed *acute pain.* Pain that is present after this period is termed *postherpetic neuralgia* (PHN) and may persist for months to years after lesions have disappeared. As age increases, the risk and duration of PHN also rise. Nearly half of the patients older than 60 years have this complication. Other complications of HZ include secondary bacterial infections, pneumonitis, and meningitis. HZ virus vaccine (Zostavax) is available for the prevention of shingles and PHN in persons 60 years or older.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes chemical burns, Bell's palsy, conjunctivitis, and trigeminal neuralgia. The blisters in poison ivy often occur in a linear "dermatomal," but they are painless.

ED EVALUATION

The diagnosis of HZ is based on history of pain and appearance of the dermatomal rash. Laboratory tests are not necessary. Scraping for a Tzanck smear or viral culture is usually negative, and a biopsy is usually required for definitive diagnosis. HZ ophthalmicus is diagnosed by slit lamp detection of corneal dendritic lesions.

ED MANAGEMENT AND DISPOSITION

A meta-analysis found that acyclovir reduces pain duration and prevalence, especially in patients 50 years of age or older (7). The recommended therapy is acyclovir 800 mg five times a day for 7 days. Famciclovir 500 mg or valacyclovir 1,000 mg tid for 7 days has also been shown to decrease the median duration of PHN (8,9). Treatment should be started within 72 hours to be effective. Symptomatic treatment with oral analgesics and Burow solution–soaked compresses three times a day is often helpful as well.

It is unclear whether adding prednisolone is beneficial (10). Corticosteroids do not change the incidence or duration of PHN, but they may improve the quality of life (time to return to usual activity,

cessation of use of analgesic agents, and time to return to uninterrupted sleep) in patients older than 50 years of age with acute HZ (11,12). A tapering dose of 60 mg/day for 7 days, then 30 mg/day for 7 days, then 15 mg/day for 7 days can be used. Relative contraindications to the use of corticosteroids include hypertension, renal insufficiency, diabetes, osteoporosis, and peptic ulcer disease. The incidence of adverse effects is higher in patients treated with corticosteroids.

The treatment of PHN includes analgesics (oxycodone), lidocaine patches, tricyclic antidepressants, (nortriptyline), and gabapentin. Lidocaine patches are very effective and should be applied to the skin rash along the affected dermatome. A referral to a pain specialist may be necessary.

Ophthalmologic consultation is indicated if the ophthalmic division of the trigeminal nerve is involved. Dissemination beyond the original dermatomes should raise the suspicion of immunodeficiency. Immunocompromised patients with severe disease should receive acyclovir 10 to 12 mg/kg IV infused over 1 hour every 8 hours. If lesions persist or there is concern for acyclovir resistance, consider foscarnet 40 mg/kg IV every 8 hours.

Hospital employees who are exposed to patients with HZ should be tested for antibody to the varicella zoster virus. Isolation for 8 to 21 days after exposure is recommended when antibody is not detected. If antibody is present, isolation is unnecessary (13). Varicella zoster immune globulin (VZIG) is recommended within 72 hours for exposed immunocompromised contacts.

Common Pitfalls

- Failure to instruct patients about measures to prevent transmission. Patients with HZ can transmit the virus as chickenpox to persons who have not already been infected.
- Failure to recognize a central cause of facial paralysis.
- Failure to recognize and treat ocular involvement.
- Failure to recognize or admit immunocompromised individuals.

ALLERGIC CONTACT DERMATITIS

Because allergic contact dermatitis is a result of delayed hypersensitivity, skin lesions may appear hours to days after exposure to the offending antigen, and it is often difficult to identify the antigen. Commonly identified etiologic agents include poison ivy, oak, and sumac; soaps; detergents; and perfumes. Pruritus is the initial symptom, which is quickly followed by erythema and vesiculation. Areas with a thin stratum corneum (such as eyelids and genitalia) may swell severely. Without treatment, symptoms may persist for 2 to 3 weeks.

Mild contact dermatitis may be treated with topical corticosteroids. For severe cases, oral prednisone (40 to 60 mg/day for 7 days) accelerates resolution of symptoms (usually within 24 to 48 hours) and poses minimal risks of adverse effects.

FIXED DRUG ERUPTION

Like HSV, fixed drug eruption causes recurrent episodes of skin lesions in one location. Unlike herpes simplex, however, fixed drug eruption generally leaves persistent slate gray to brown hyperpigmentation after the attack resolves. The most commonly implicated drugs include phenolphthalein (e.g., Ex-Lax, Feen-A-Mint), tetracycline, sulfa, and barbiturates. Symptoms usually arise 1 to 2 days after ingestion. Pruritus generally occurs first, followed by the appearance of clusters of vesicles or bullae in a hyperpigmented macule. The process resolves in 2 to 3 weeks, after discontinuation of the offending agents.

OTHER CAUSES OF VESICULAR ERUPTIONS

Dyshidrotic eczema (pompholyx) usually occurs on the medial and lateral aspects of the fingers and sometimes on the palms and soles. It is intensely pruritic and responds to topical corticosteroids. If severe, oral steroids can be used.

The vesicular eruption of tinea pedis may usually be diagnosed clinically by potassium hydroxide staining of vesicle fluid. Treatment is with a topical antifungal agent such as clotrimazole.

Accompanying involvement of the hands is often an eczematous reaction.

Atopic dermatitis is generally accompanied by a personal or family history of eczema, allergic rhinitis, asthma, or urticaria. Nonetheless, the eruption is usually precipitated by physical irritation (wool gloves, soap, and water) or emotional stress. Treatment with topical steroids is effective.

Dermatitis herpetiformis (unrelated to the herpes viruses) may be confused with scabies or neurotic excoriations. It generally presents with broken, excoriated vesicles on an erythematous base. It usually begins on extensor surfaces and is pruritic. Treatment is with dapsone and oral antihistamines.

INDIVIDUAL OR DISSEMINATED VESICLES

Varicella

Varicella (chickenpox) is primarily a disease of childhood, but it is not uncommon in adults. It is acquired by direct contact with infected lesions or inhalation of airborne droplets. Varicella begins with replication of the virus at the sites of contact and is followed by the development of a primary viremia, which establishes replication in the reticuloendothelial system. A secondary viremia occurs after 1 week, which disseminates the infection to the skin. The virus then establishes latency in the sensory ganglion. Reactivation of the latent infection causes HZ.

CLINICAL PRESENTATION

Varicella presents with a rash, low-grade fever, and malaise. The lesions start as erythematous macules, progress to vesiculation with the classic “dew drop on a rose petal” appearance, become pustules, and finally crust over (Fig. 172.2). The hallmark of varicella rash is the simultaneous presence of lesions in all stages of development. The lesions usually appear on the trunk and face and then spread to other areas of the body, including scalp, mouth, ears, and genitalia. They are intensely pruritic. There may be a history of exposure 10 to 14 days before the rash. Varicella is highly contagious. Second attack

rates for this virus may reach 90% for susceptible household contacts. Patients are considered infectious 2 days before the appearance of the rash until all vesicles have formed crusts, which is usually 5 to 6 days after the first appearance of the eruption. The severity of the illness varies from individual to individual and is inversely related to age. An attack of chickenpox usually confers lifelong immunity, although secondary attacks can happen. Varicella vaccine is now available in the United States and is approved for children and adults.

FIGURE 172.2 Varicella. The lesion starts as a 2- to 4-mm red papule, then develops into an irregular outline (rose petal) as a thin clear vesicle appears on the surface (dewdrop).

Varicella is usually a benign illness in immunocompetent patients. Immunocompromised individuals or those using immunosuppressive drugs, especially systemic corticosteroids, are at a greater risk for complications (14). The most common complication in children is secondary bacterial skin infections after scratching, leading to a cellulitis. Varicella pneumonitis is rare in children but is the most common serious complication in adults. It can present with

tachypnea, cough, fever, and pleuritic chest pain leading to acute respiratory distress syndrome. Other complications include hepatitis, nephritis, orchitis, and encephalitis. Encephalitis in children is usually self-limited and includes cerebellar ataxia, nystagmus, and headache. Adult encephalitis has a mortality rate of 35% (15). Reye syndrome is an encephalopathy with fatty liver and is associated with salicylate use. Twenty to 30% of Reye syndrome cases are preceded by varicella (16).

Varicella during pregnancy poses a risk to both mother and child. The highest risk for fetal varicella syndrome is between 13 to 20 weeks of gestation. It is characterized by small infant size, cicatricial skin lesions, limb hypoplasia, and other anomalies. For newborns, the risk of infection and complications is greatest when the mother develops chickenpox 5 days before to 2 days after delivery. These infants have an increased chance of dissemination as they lack both maternal antibodies and a mature immune system. They should be given VZIG. VZIG is effective in preventing chickenpox in exposed susceptible, especially immunocompromised individuals (Table 172.2).

TABLE 172.2
Varicella Zoster Immune Globulin Indications

Immunocompromised children
Newborns whose mother had varicella 5 d before to 2 d after delivery
Infants exposed in nursery
All premature infants <28 wks
Susceptible pregnant women
Healthy or immunocompromised adolescents and adults who are unvaccinated and susceptible postexposure prophylaxis[a]

[a]Administration may prevent or reduce intensity of disease. It is not indicated once clinical disease has developed. VZIG may be administered within 96 hr after exposure.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes disseminated zoster, disseminated herpes simplex, eczema herpeticum, and folliculitis.

ED EVALUATION

Diagnosis is usually made clinically. Laboratory tests are not necessary. A Tzanck smear and viral culture may aid in making the diagnosis. A chest x-ray should be obtained if respiratory symptoms develop. A lumbar puncture is needed if encephalitis is suspected.

ED MANAGEMENT AND DISPOSITION

Treatment of varicella in healthy children is optional because the disease is self-limited. Symptoms can be managed with supportive care consisting of daily baths and soaks to destroy the virus. Close cropping of the fingernails, calamine lotion, and antihistamines to avoid excessive excoriations can provide relief. Isolate the patient, especially from immunocompromised hosts. Aspirin and Caladryl lotion, which can lead to an anticholinergic response from excessive skin absorption, should be avoided. Acyclovir should be considered in children up to age 12 who are being treated with corticosteroids or long-term salicylate therapy, or those with chronic cutaneous or pulmonary diseases (17). Acyclovir, if started within 24 hours of rash development, has been shown to reduce the number of lesions, the duration of fever, and pruritus. Treatment after the first day of illness is of no value in uncomplicated cases of varicella (18). All immunocompromised individuals with varicella should be hospitalized for intravenous acyclovir (Table 172.3). Hospitalization is also required for skin sepsis, pneumonitis, dense or hemorrhagic rash, and bleeding.

TABLE 172.3
Treatment of Varicella

Acyclovir—adults—800 mg 5×/d for 7 d
13–18-yr-olds—20 mg/kg/dose PO qid for 7 d
Peds—20 mg/kg/suspension PO qid for 5 d (max. 800 mg PO qid)
Immunocompromised—10 mg/kg IV q8hr slowly over 1 hr[a]
Famciclovir—500 mg PO tid for 5–7 d[b]
Valcyclovir—1,000 mg PO tid for 5–7 d[b]

[a]With rapid IV injection, acyclovir crystals may precipitate in the collecting ducts causing renal toxicity, therefore infuse slowly over 1 hr and maintain adequate hydration.
[b]Famciclovir and Valcyclovir have not been evaluated in children.

COXSACKIEVIRUS AND ECHOVIRUS INFECTIONS

Coxsackievirus and echovirus infections may cause papulovesicular lesions that are evenly spread across the face and torso. Associated symptoms may include fatigue, malaise, fever, vomiting, and diarrhea. Resolution occurs spontaneously in 10 to 14 days, and treatment is symptomatic.

Hand, foot, and mouth disease caused by coxsackieviruses presents with tender, flat-topped, whitish vesicles 3 to 4 mm in diameter on the palms and soles and in the mouth. It is commonly associated with mild systemic complaints. The duration is generally 4 to 5 days and no treatment is necessary.

INSECT BITES

Vesiculobullous skin lesions may occur as hypersensitivity reactions to insect bites, commonly those of fleas, bedbugs, and mites. A clue to the diagnosis is a linear or grouped pattern of lesions; some may have central puncta. Treatment is with topical corticosteroids and oral antihistamines, and avoidance of further contact with the insect.

CRITICAL INTERVENTIONS

- Initiate acyclovir within 24 hours of the onset of rash in adult varicella and within 72 hours of onset of HZ.
- Obtain ophthalmology consult for patients with herpetic keratitis due to herpes simplex or with involvement of the ophthalmic division of the trigeminal nerve in HZ.

Common Pitfalls

- Failure to instruct patients about measures to prevent transmission of varicella.
- Failure to admit immunocompromised patients with varicella.

CHAPTER 173

Purpuric Eruptions

Christian M. Neff and Stephen C. Hartsell

The term *purpura* (Latin meaning “purple”) refers to any skin or mucous membrane eruption resulting from bleeding into the skin. The defining characteristic of purpuric lesions is the absence of blanching, whereas color persists with compression.

Broadly speaking, purpura may result from abnormalities in primary or secondary hemostasis (thrombocytopenia, abnormal platelet function, clotting factor deficiency, abnormal clotting factor function) or disruptions in vascular integrity (trauma, infection, vasculitis, medications, collagen disorders). Deficiencies in platelet number or function are a far more common cause of purpuric skin lesions than are defects or deficiency of a single procoagulant clotting factor (1).

The etiologies of purpura are extensive and range from the trivial (e.g., actinic purpura in the elderly, “bruises” secondary to minor trauma) to the life-threatening (e.g., meningococcemia, thrombotic thrombocytopenic purpura [TTP]) (Table 173.1). Rapid differentiation of benign from potentially serious causes of purpura is essential, as it allows for the initiation of emergent treatments where indicated while minimizing unnecessary evaluation.

TABLE 173.1
Causes of Purpura by Morphologic Characteristics

Nonpalpable Purpura

Thrombocytopenia

- Decreased platelet production (bone marrow disorders): irradiations, medications (**Table 173.2**), bone marrow failure, neoplasm
- Increased platelet destruction: immune-mediated (ITP, SLE, CLL, HIV, medications), posttransfusion, neonatal, nonimmune (consumptive coagulopathies, DIC, TTP, HUS, purpura fulminans, artificial surfaces)
- Platelet sequestration: hypersplenism, hypothermia

Abnormal platelet function

- Congenital platelet function defects
- Acquired platelet function defects: medications (see Table173.2), renal/hepatic insufficiency

Mechanical purpura

- Local trauma
- Increased hydrostatic pressure: suction, CPR, high altitude, Valsalva, ligature, strangulation

Factitious purpura

- Self-abuse: Munchhausen's disease, religious stigmata, Gardner-Diamond syndrome

Disorders of vascular connective tissue

- Actinic (senile) purpura
- Metabolic purpura: scurvy, corticosteroid use
- Connective tissue syndromes: Ehlers–Danlos syndrome, osteogenesis imperfecta, Marfan syndrome

Pigmented purpuric disease

Nonpalpable or Palpable

Infectious (3,4)

- Bacterial: Neisseria, Haemophilus, Streptococcus, Rickettsia, Bordetella, Capnocytophaga, Brucella (5)
- Viral: enterovirus, coxsackie, respiratory syncytial virus, rubella, measles, ECHO virus, hepatitis A, hepatitis B, parvovirus B19, cytomegalovirus, varicella, viral hemorrhagic fevers
- Fungal: Candida, Trichosporon
- Protozoal: strongyloides, malaria

Palpable

Dysproteinemias

- Waldenström macroglobulinemia
- Cryoglobulinemia, cryofibrinogenemia

Purpura fulminans

- Warfarin-induced skin necrosis
- Protein C or protein S deficiency
- DIC
- Severe infections such as meningococcemia

Vasculitides

- Hypersensitivity vasculitis: Henoch-Schönlein and other allergic purpuras, collagen vascular disorders, infections (e.g., streptococcus, hepatitis B, cytomegalovirus, Epstein–Barr virus), dysgammaglobulinemias, malignant neoplasms, cryoglobulinemia, serum sickness
- Granulomatous vasculitis: Wegener, giant cell

Microvascular occlusion

- Platelet plugs
- Cholesterol embolization
- Embolus from atrial myxoma, septic or marantic endocarditis
- Hemoglobinopathy occlusion

SLE, systemic lupus erythematosus; CLL, chronic lymphocytic leukemia; DIC, disseminated intravascular coagulation; HUS, hemolytic uremic syndrome.

CLINICAL PRESENTATION

Patients with purpura may present to the emergency department due to concern about the rash itself or because of symptoms accompanying the rash. Regardless of the appearance of the rash or associated symptoms and signs, the presence of spontaneous bleeding ("wet" purpura) is a grave sign requiring immediate intervention (2). The cause is usually thrombocytopenia, and the emergent treatment is platelet transfusion. The immediate threat to life is intracranial hemorrhage (2). Severe anemia and shock from blood loss are possible but not common.

Patients without spontaneous bleeding ("dry" purpura) may have extensive petechiae or ecchymoses on the skin but are in less immediate danger. However, spontaneous bleeding may develop at any time, so rapid determination of the cause is still indicated.

Purpuric lesions vary in color, size, consistency, shape, associated erythema, and distribution. These morphologic variations may provide clues to the etiology of the lesions. Purpuric lesions must have a shade of color consistent with hemorrhage. Lesions may be red, blue, purple, yellow-brown, green, or black (1). Lesions are classified by their varying sizes. Lesions <3 mm are termed *petechiae,* whereas lesions >3 mm are termed *purpura* (3). Lesions >1 cm in diameter are termed *ecchymoses* (1). They may be flat and nonpalpable or raised and palpable, with a round or a retiform (branching) shape. Associated erythema may be prominent or absent. The distribution may be localized or generalized. Purpura may appear with a variety of other lesions, depending on the underlying cause and stage of development.

DIFFERENTIAL DIAGNOSIS

The etiologies of purpura are extensive and they encompass hematologic, dermatologic, infectious, traumatic, and rheumatologic entities (see Table 173.1) (1). In addition, purpura may be caused by a variety of drugs, which can cause small-vessel or platelet

disorders by direct toxicity, inhibition of function, or immune-mediated mechanisms (Table 173.2) (6,7).

TABLE 173.2
Drugs Causing Purpura

Analgesics	
	Acetylsalicylic acid, acetaminophen, nonsteroidal anti-inflammatory drugs, codeine
Antibiotics	
	Antituberculous agents, penicillins, sulfonamides, chloramphenicol, nitrofurantoin, tetracyclines, erythromycin, cephalosporins, aminoglycosides, streptomycin
Anticonvulsants	
	Barbiturates, carbamazepine, diphenylhydantoin, primidone, valproate sodium, lamotrigine
Antihypertensives	
	Methyldopa, reserpine
Anticoagulants	
	Coumadin, heparin, GIIB/IIIa inhibitors
Cardiovascular agents	
	Atropine, quinidine, digitalis, nitroglycerin, propranolol, acenocoumarol
Antirheumatics	
	NSAIDs, gold, corticosteroids, sulfasalazine
Diuretics	
	Thiazides, furosemide, spironolactone
Hypoglycemics	
	Tolbutamide, chlorpropamide, metformin
Sedatives–hypnotics	
	Meprobamate, phenobarbital, chlordiazepoxide
Antipsychotics, antidepressants	
	Tricyclic antidepressants, phenothiazines
Miscellaneous	
	Metoclopramide, antimetabolites, chemotherapeutic agents, ethanol, allopurinol, estrogens, oral contraceptive pills, heroin, quinine, hydroxychloroquine, antihistamines, guaifenesin, clofibrate, chlorpheniramine, arsenicals, cimetidine, griseofulvin, iodides, dextroamphetamine, bismuth, organic hair dyes, menthol, insecticides, benzene, metal compounds

The lesions of purpura are characteristic and difficult to mistake for other types of lesions. Other erythematous rashes, such as viral

exanthems and urticaria, can be differentiated from purpura by their light-red color, and in that they blanch with pressure. Similarly, telangiectases and hemangiomata are discrete collections of abnormally dilated blood vessels that appear bright red and usually blanch with pressure. Diascopy, the use of a glass slide to apply pressure over a lesion, is a simple visual method to differentiate lesions due to vascular dilation (which blanch with pressure) from those due to purpura (which do not).

Some lesions are purpuric but do not reflect an underlying illness, and are sometimes classified as mechanical or factitial purpura (3). Purpuric lesions may be created by trauma or increased hydrostatic pressure in normal skin. Examples of mechanisms potentially resulting in purpuric lesions are self-inflicted trauma, forceful or protracted vomiting or sneezing, strangulation, suction, and coining (3,8).

ED EVALUATION

The initial focus of the emergency department evaluation of purpura is to identify and initiate treatment of any life-threatening disorders. Empiric, potentially life-saving treatments (e.g., platelet transfusion or intravenous antibiotics) should be initiated based on the presumptive diagnosis and preliminary laboratory results without awaiting definitive diagnosis. Intracranial hemorrhage should be considered in any patient presenting with purpura associated with neurologic abnormalities, and emergent treatment, usually with platelet transfusion, should be initiated. Meningitis and/or meningococcemia are suggested by purpura associated with fever, altered mental status, headache, neck stiffness, or systemic toxicity, and require emergent resuscitation and treatment with antibiotics. While the initial rash associated with meningococcal infection may be a maculopapular eruption resembling a wide variety of viral exanthems, more than 50% of patients have petechiae or purpura upon presentation (9,10). Active bleeding or wet purpura should likewise be considered a dermatohematologic emergency. Attention should be paid to the presence of bleeding gums, epistaxis,

intraocular hemorrhage, guaiac-positive stool, menorrhagia, or hematuria. Marked thrombocytopenia is almost universally the cause of wet purpura, and platelet transfusion should not be delayed while awaiting laboratory confirmation when bleeding is significant.

In patients presenting with purpura without signs or symptoms of a life-threatening emergency, evaluation should be pursued to elucidate the cause of the purpura. A directed patient history should include recent infections, recent medication or drug ingestion, irradiation or chemical exposure, and systemic symptoms. History of abnormal or spontaneous bleeding (frequent epistaxis, bleeding after dental or other minor procedures, menorrhagia, etc.) should be elicited. Questions relating to hepatic, renal, rheumatologic, or hematologic disease, malignancy, immunosuppression, or human immunodeficiency virus (HIV) infection are also pertinent. A complete list of medications and allergies should be obtained. Except for hereditary coagulation disorders, which rarely present as purpura, and rare hereditary thrombocytopenias, the family history is usually unremarkable. The social history should include questions regarding alcohol and drug use and risk factors for HIV.

Initial physical examination should pay particular attention to markers of serious systemic illness such as fever and other vital sign abnormalities, altered mental status, meningismus, or active bleeding.

Characterization of the purpuric lesions may provide clues to etiology. The distribution of the lesions may suggest specific disease processes. Senile or actinic purpura occurs on sun-exposed areas, usually the forearms, of elderly patients. Vasculitic purpura is usually symmetric and predominates in the lower extremities (e.g., Henoch-Schönlein purpura) (Fig. 173.1). A more generalized distribution of discrete petechiae may be noted when purpura is associated with bacterial illness such as meningococcemia or subacute bacterial endocarditis. Purpuric lesions in thrombocytopenia tend to occur in areas of minor trauma or areas of pressure, such as the belt line or over bony prominences. The purpura of scurvy classically appears as perifollicular petechiae, whereas that of Rocky Mountain spotted fever begins over the distal

joints and spreads centrally. The lesions of purpura fulminans are large, symmetric ecchymoses of the lower extremities and buttocks, often with infarcted areas or bullae.

FIGURE 173.1 Henoch-Schönlein purpura. (Courtesy of Dr. Sate Hazma, dermatopathology fellow, University of Birmingham, and Dr. Amy Theos, Assistant Professor, Department of Dermatology, University of Alabama at Birmingham.)

Lesions may be categorized into groups of likely diagnosis based on size, palpability, morphology, and the associated erythema (1,3). Nonpalpable purpuric lesions result primarily from a decrease in the number of functioning platelets or from mechanical insults to the vascular barrier. Nonpalpable purpuric lesions >1 cm may be caused by major trauma or minor trauma coupled with a procoagulant defect or poor dermal vessel support (1). Palpability results from edema, which most commonly results from inflammation, but also may be seen with microvascular occlusion and ischemia (1). Erythema is usually present with inflammation and absent with microvascular occlusion and ischemia.

When bacterial infections cause purpura, the lesions may have a central purulent papule (e.g., disseminated gonococcemia). Immune-

mediated vasculitides often have lesions of erythema, bullae, or urticaria in association with palpable purpura. Coumadin-associated vasculopathy may result in necrotizing ecchymoses.

The physical examination may further reveal specific abnormalities in certain causes of purpura. In thrombocytopenia, the optic fundi and mucous membranes may show petechiae. Painful joint effusions may accompany various types of immune-mediated purpura, disseminated gonococcemia, and coagulation disorders. Lymphadenopathy or lesions characteristic of Kaposi sarcoma may be indicators of HIV seropositivity, which may present with purpura in up to 9% of cases (11). Lymphadenopathy may also be found in patients with lymphoma, infectious mononucleosis, and leukemia. Splenomegaly (as well as other forms of hypersplenism) may also be noted in these same illnesses but is absent in most other types of thrombocytopenic purpura (e.g., idiopathic thrombocytopenic purpura) and coagulation defects (1).

All but trivial causes of purpura (e.g., actinic, mechanical, factitial) require laboratory studies to elucidate the underlying cause. As thrombocytopenia is the most common cause of clinically significant purpura, a platelet count is a required component of initial testing. Easy bruising may be noted with platelet counts of 30,000 to 50,000/μL, whereas spontaneous ecchymoses or petechiae usually do not appear until the platelet count is less than 30,000/μL. Internal bleeding, including intracranial hemorrhage, rarely occurs with platelet counts $>$10,000/μL (12). For example, in a study of patients with thrombocytopenia secondary to immune thrombocytopenia (ITP), minimal bleeding after trauma was uncommon unless the platelet count was less than 60,000/μL, whereas self-limited bleeding, spontaneous bleeding requiring intervention (e.g., nasal packing for epistaxis), and severe life-threatening bleeding did not occur until platelet counts were $<$40,000, $<$12,000, and $<$6,000/μL, respectively (13).

A complete blood count with differential serves as a screen for anemias, bone marrow disorders, various malignancies and infection. The peripheral blood smear screens for abnormal red blood cell and platelet morphology which may be indicative of

hemolysis and various platelet abnormalities, respectively. Prothrombin time and activated partial thromboplastin time screen for coagulation or mixed platelet and/or coagulation disorders (14,15). Determination of bleeding time may be of limited use in the emergency department in confirming platelet dysfunction or vascular disorders. The fibrinogen level, along with fibrin–fibrinogen degradation products (FDP, D-dimer), may also be useful (14). Because therapy with blood products is sometimes necessary and their use may confound subsequent diagnosis, extra tubes for type and screen and for other platelet and coagulation assays should be obtained before treatment.

On subsequent (usually inpatient) evaluation, the following tests may be indicated, depending on the suspected etiology: bone marrow aspiration, skin biopsy, bleeding time, autoimmune disease screening tests, clotting factor assays, and platelet function tests (15).

KEY TESTING

- CBC
- PT/INR, PTT
- Peripheral blood smear
- Fibrinogen level, fibrin degradation products
- D-dimer

ED MANAGEMENT

First, life-threatening complications of spontaneous bleeding should be stabilized, and efforts should be made to ascertain the cause of purpura. As described, the history, physical examination, and laboratory studies should allow rapid determination of the category of illness causing the purpura and associated symptoms.

When thrombocytopenia is the cause of purpura, platelet transfusion should be considered only when there is evidence of abnormal bleeding. Generally, each unit of platelets may be expected to raise the platelet count by about 5,000 to 10,000/μL (16). Spontaneous mucous membrane or CNS bleeding can usually

be controlled when the platelet count is restored to more than 20,000/μL. Platelet transfusion is relatively contraindicated in disorders caused by intravascular thrombosis such as TTP because platelets may contribute to further thrombosis. In TTP, plasma exchange is the only treatment for which there is firm data on its effectiveness (17). When immune-mediated thrombocytopenia is likely, as in immune thrombocytopenic purpura or posttransfusion purpura, the half-life of transfused platelets is short (hours) compared with that for other disorders (days) (2). In these cases, alternative therapy, such as corticosteroids, immunoglobulins, or splenectomy may eventually be indicated (12,18).

Coagulopathies presenting with spontaneous bleeding may be treated by replacement of specific coagulation factors. In acquired coagulopathies from coumadin or liver disease, vitamin K is indicated. Fresh frozen plasma may be helpful in a variety of coagulopathies and thrombolytic disorders when specific factor replacement is not available or cannot be determined (19).

If purpura is thought to be due to a drug (Table 173.2) regardless of the suspected mechanism, that drug should be discontinued. Anticoagulants or platelet inhibitors (in proper dosages) may be reinstituted, if indicated, when the disorder is controlled.

Specific therapy directed to underlying disorders should be initiated once the etiologic factors have been defined and a diagnosis established.

CRITICAL INTERVENTIONS

- Intervene immediately with the combination of purpura and spontaneous bleeding (wet purpura).
- Intracranial hemorrhage should be considered in patients presenting with purpura and associated neurologic symptoms.
- Meningococcemia and/or meningitis suggested by purpura associated with fever, altered mental status, meningismus, or systemic toxicity represent a life-threatening emergency requiring immediate treatment.

DISPOSITION

Because purpura may reflect hematologic, rheumatologic, traumatic, or infectious disorders, consultation is obtained from appropriate specialists once trivial causes of purpura have been excluded. When the diagnosis is unclear, a dermatology consultation is warranted. Because the underlying disorders that are responsible for purpura often have the potential for progressing to life-threatening emergencies, patients with purpura are often admitted to the hospital for confirmation of the diagnosis and definitive treatment. Patients presenting with spontaneous bleeding or life-threatening complications, such as CNS hemorrhage or septic shock, require immediate hospital admission, usually to an intensive care unit.

Emergency transfer of patients with life-threatening complications of purpuric illness is indicated when the needed blood products, specialty consultation, or level of care are not available. Stabilization with intravenous fluids and emergently indicated blood products (when available) should be accomplished before transfer, after consultation with the accepting physician. Patients whose illness may progress rapidly should be considered for air ambulance transfer when ground transport times would be prolonged.

Common Pitfalls

- Failure to recognize the signs and symptoms of emergent conditions associated with purpura, such as intracranial hemorrhage and serious bacterial infections, may result in devastating delays in treatment.
- Failure to consider the trivial causes of purpura may result in unnecessary time and expense spent in pursuing a diagnostic workup.
- Drugs are a common cause of purpura and, unless an adequate history of drug exposure is obtained, the causal agent may initially be missed.
- Dismissing associated mucous membrane or spontaneous bleeding (wet purpura) may result in delay in therapy (usually

platelet transfusion) and increased risk of life-threatening hemorrhage.
- Premature administration of drugs or blood products may delay laboratory diagnosis, and in some cases, may worsen the disease process responsible for the purpura.

CHAPTER 174
Urticaria

Carol A. Freire, Dana E. Robinson, and Theodore A. Christopher

Urticaria, or hives, is a commonly occurring vascular reaction of the superficial dermis of the skin resulting in pruritic wheals that form in response to a triggering stimulus. *Acute* urticaria is characterized by symptomatic attacks lasting less than 6 weeks and *chronic* urticaria is characterized by attacks that last 6 weeks or longer, with episodes of the latter tending to be less frequent and less severe than the former. One of the most common skin lesions seen in emergency medicine, urticaria can occur in any age group, but children and young adults are more commonly affected. In a majority of cases, a trigger cannot be determined (1).

The etiologies of urticaria are extensive and complex in nature (2). Generally, they may be broken down into several broad categories based on their underlying pathophysiology (Table 174.1). In most cases, however, the cause of urticaria is primarily mast cell degranulation, which releases histamine as well as a wide array of vasoactive peptides. The released histamine binds to receptors (predominantly H_1) in the microvasculature, especially the postcapillary venules, causing superficial local edema (wheals) and vasodilation (flare). Histamine also binds to H_1 receptors in the histamine-selective (itch-specific) C nerve fibers, making them more irritable and causing pruritus. In many cases, this reaction is allergic in nature and mediated by IgE, following prior sensitization (type I hypersensitivity), but degranulation can also occur by other immunologic and nonimmunologic routes (3,4). Histologically, urticaria involves only the superficial dermis, distinguishing it from

angioedema, which involves the deeper dermis. Perivascular lymphocytic and mast cell infiltration are also features.

TABLE 174.1
Classification of Urticaria

Allergic	Autoimmune
Food	Hormonal
Most drugs	Psychosomatic
Insect bites and stings	Physical
Contact urticaria	Dermographism
Pseudoallergic	Cholinergic
Aspirin and NSAIDs	Solar
Dyes and food additives	Delayed pressure
Irritant	Aquagenic
Plants	Vibratory
Opioids	Cold
Infection	Idiopathic
Viral	
Bacterial	
Parasitic	

NSAID, nonsteroidal anti-inflammatory drug.

It should be noted that type I hypersensitivity occurs in two phases —the immediate reaction, which occurs within the first hour after antigen challenge, and the late phase, which occurs several hours later, usually peaking at 3 to 9 hours. The late phase is not always noticeable, and the delay time, severity, and duration are variable and depend on the allergen dose. This late phase is due to continued synthesis and release of vasoactive substances by mast cells and can produce much more involved and long-lasting edema than the immediate wheals.

High-quality estimates of the prevalence of either acute or chronic urticaria are lacking. A recent survey conducted in Germany showed an 8.8% (95% CI 7.9% to 9.7%) lifetime prevalence for urticaria of any type and a 1.8% (95% CI 0.6% to 1.1%) lifetime prevalence for chronic urticaria (5). Chronic urticaria in this population afflicted women (70.3%) more than men. Chronic urticaria is also notable for

being diagnosed later in life, most often in the third or fourth decade.

CLINICAL PRESENTATION

Urticaria is characterized by slightly raised, sharply defined, erythematous, blanching wheals. They are typically pruritic, though usually nontender. The wheals may appear anywhere on the body and are often localized to the site of irritation but can cover large areas of the body with systemic triggers such as food allergies. The color of the wheals ranges from pink to red and central clearing may be present. The shape can be round, ovoid, or ring like, commonly with serpiginous borders, and multiple wheals may be aggregated into large plaques, giving an irregular appearance. Wheal size can range from a few millimeters to plaques that cover significant regions of the body. One of the hallmarks of urticaria is that the affected region can change size and new areas may become affected over time. Individual wheals typically last less than 8 to 12 hours; a longer persistence suggests urticarial vasculitis or delayed pressure urticaria (see below).

Table 174.2 summarizes the types and triggers of urticaria. Foods and drugs are the most common causes of acute urticaria. They act through both immunologic and nonimmunologic mechanisms (6). Among foods, nuts, berries, shellfish, chocolate, fish, tomatoes, and eggs are frequent causes of acute urticaria. In urticaria of chronic duration, milk, cereals, beef, pork, cheese, garlic, onions, and spices may be responsible. Food additives, both natural and synthetic, are also important etiologic factors. Reaction timing can be anywhere from within minutes of ingestion to many hours later. Worthy of particular mention is scombroid poisoning (7), which is a type of food poisoning that is classically associated with the *scombridae* family of fish such as mackerel and tuna, but can be caused by many other species. These fish contain large quantities of the amino acid histidine in their muscle tissue, which is converted to histamine by bacterial histamine decarboxylase in improperly stored fish.

TABLE 174.2
Agents Known to Cause Urticaria

Medications
Aspirin, NSAIDs
Antibiotics, particularly penicillin and other β-lactams
Iodides
IV contrast dyes
Many other drugs
Foods
Dairy products
Eggs
Wheat
Legumes (including peanuts and soy)
Tree nuts
Seafood (fish, molluscs, crustaceans)
Fruits (particularly berries)
Environment
Dander
Dust
Molds
Contact
Latex
Nickel
Cosmetics and lotions
Household cleansers
Soaps and shampoos

NSAID, nonsteroidal anti-inflammatory drug.

Many medications have the potential to cause an allergic response and should always be considered as a possible cause of urticaria. Antibiotics, particularly the β-lactams, and aspirin/NSAIDs are the most common drugs that cause urticaria, with aspirin and NSAID intolerance having been identified in 20% to 40% of patients with chronic urticaria. Urticaria may occur from 15 minutes to 24 hours (average 1 to 4 hours) after aspirin ingestion. The condition usually resolves within a day or two but may last up to 2 weeks. The pathogenic mechanism of aspirin intolerance is unclear, but a likely hypothesis is that mast cell degranulation is due to rapid PGE_2

depletion by drugs capable of inhibiting COX-1 and is not an allergic reaction. It usually appears in the third decade of life and is often accompanied by wheezing, increased bronchial secretions, rhinorrhea, and flushing (8).

With physical urticaria, wheals and itching develop at sites of a physical stimulus (9). Urticaria factitia or dermatographism is defined as a whealing reaction of the skin within 10 minutes of stroking or scratching the skin. Clinically, dermatographism occurs within seconds after stimulation and fades within 30 minutes. It is often a response to contact with seatbelts or brassieres. In contrast to dermatographism, delayed pressure urticaria is a response to more sustained physical pressure applied to the skin (10). It produces itchy, often painful wheals. These lesions can be delayed up to 12 hours and may last several days. Common causes are tight-fitting garments, prolonged walking (feet), or sitting (buttocks).

Cholinergic urticaria is characterized by pruritic, follicular-bound, 1- to 4-mm wheals surrounded by a red flare and produced within 15 minutes of a stimulus. Exercise, hot baths, spicy food, and emotional stress can precipitate episodes of cholinergic urticaria, which usually begins on the upper thorax and neck before spreading to the entire body, often sparing the palms and soles. The exact pathophysiology is unclear but may involve an autoimmune reaction to a sweat antigen. Clinically, patients can present with varied symptoms, including lacrimation, salivation, diarrhea, abdominal pain, weakness, flushing, and headache. Rarely, severe, life-threatening symptoms (e.g., angioedema, bronchospasm, vascular collapse, and hypotension) can occur.

Solar urticaria presents as a whealing response within 10 minutes in skin exposed to ultraviolet or visible irradiation from any source, though UVA is most commonly implicated. In addition to hives, symptoms may include wheezing, dizziness, and (rarely) hypotension; all resolve within 1 to 3 hours after the light stimulus is removed (11).

Cold urticaria occurs on exposed areas, such as the face and hands, and is commonly induced by swimming. It occurs within minutes of exposure, usually during rewarming, and can be elicited by placing

an ice cube on the skin, holding cold objects in the hand, or drinking cold fluids (leading to lip swelling). It also may be associated with other symptoms, including syncope and shock.

Other physical urticarias include generalized aquagenic urticaria, which is induced by contact with water of any temperature; vibratory urticaria, in which localized swelling occurs within minutes of local vibration (e.g., lawn mowing, power tool use); and adrenergic urticaria, an extremely rare variant of stress-related urticaria, characterized by blanched, vasoconstricted skin surrounding very small erythematous wheals. The inhalation of allergens may also induce hives, but respiratory symptoms typically predominate. Common aeroallergens include household dust, pet dander, pollens, and mold.

Insect bites can cause widespread urticarial lesions that are distinct from the common local erythematous and vesicular reaction. Wasps, hornets, fleas, gnats, mites, mosquitoes, and bedbugs are common offenders.

Urticaria can also occur during a blood transfusion. This reaction is known to be an antibody-mediated response to a donor's plasma proteins and is not a signal of transfusion-related hemolysis. This occurrence is not an indication to stop the transfusion, and treatment with an antihistamine will suffice.

Urticaria can also be caused by an infection, particularly in children. Bacterial, fungal, viral (especially the prodrome of hepatitis A, B, and C), and parasitic agents have all been implicated, some of which are thought to be a likely cause for urticarias of chronic duration. In most cases, urticaria does not appear to be related to hypersensitivity to the infectious agent. The exception is children in whom viral illnesses commonly cause a rash that resembles urticaria. These lesions typically resolve with resolution of the viral infection.

Contact urticaria is whealing of the skin due to exposure to certain substances in susceptible patients. A diverse range of agents have been implicated, including food, metals (nickel, platinum, rhodium), and hair-care products. Of particular concern to health care workers is the emergence of latex allergy, which presents as a local or generalized urticaria but can rapidly progress to angioedema and

anaphylaxis. For this reason, many hospitals are now moving toward a completely latex-free environment.

Pruritic urticarial papules and plaques of pregnancy (PUPPP) is the most common skin condition associated with pregnancy (12). The disorders are often seen in the third trimester or (rarely) in the early postpartum period. These small (1- to 2-mm) lesions appear suddenly on the abdomen and can spread symmetrically to include the trunk and extremities, often coalescing into large plaques. The face, palms, and soles of the feet are usually spared. The etiology is unknown, but may involve connective tissue damage in the striae distensae. They are not associated with increased fetal or maternal mortality or morbidity and usually clear within 1 week of delivery. The wheals and pruritus of PUPPP are not relieved with antihistamines and are instead treated with topical corticosteroids.

Serum sickness is a type III hypersensitivity reaction that can cause urticaria and is of particular concern as more monoclonal antibody therapies have been developed. Symptoms normally appear 7 to 10 days after serum administration. Patients commonly present with fever, chills, rash, and urticaria. Glomerulonephritis is common.

Finally, several underlying systemic diseases may be responsible for unexplained chronic urticaria. Systemic lupus erythematosus, acute febrile neutrophilic dermatosis (Sweet syndrome), bullous pemphigoid, reticular erythematous mucinosis, Schnitzler syndrome, cutaneous mastocytosis (urticaria pigementosum), urticarial vasculitis, and cryopyrin-mediated autoinflammatory disorders are all recognized causes (13).

DIFFERENTIAL DIAGNOSIS

Uncomplicated urticaria can be most easily differentiated from other conditions by the characteristic painless, pruritic, slightly raised wheals. If the history and physical examination reveals findings that are suspicious for an underlying cause (e.g., thyroid disease or infection), additional tests and consultation may be warranted. Although useful for avoiding the trigger in the future, differentiating between the various causes of urticaria is normally not necessary as

the treatment in the emergency department (ED) is identical for all forms of urticaria.

Some differential diagnoses worth mentioning are as follows.

Angioedema involves the deeper dermis and mucous membranes and typically presents as a swelling of the face (especially the lips and eyes), extremities, and/or genitalia. It can occur concurrently with urticaria. It is often associated with abdominal symptoms and is more often life threatening. The two most common causes of angioedema are angiotensin-converting enzyme inhibitors and hereditary angioedema. Chapter 176 of this text covers angioedema.

Urticarial vasculitis causes lesions that may be clinically indistinguishable from urticaria, but the individual wheals last from 24 to 72 hours, are less likely to be pruritic, and may be painful or associated with a burning sensation. Secondary pigmentation and scaling are common, as are systemic symptoms such as fever and arthralgia.

Urticaria pigmentosa is a cutaneous mastocytosis that presents as disseminated tan or brown papules that form wheals within 10 minutes of vigorous rubbing with a blunt instrument (Darier sign).

KEY TESTING

- No routine laboratory testing is recommended for uncomplicated urticaria that responds to antihistamines.
- Additional tests and consultation may be warranted, depending on the findings of the history and physical examination.

ED EVALUATION

Patients must be carefully evaluated and observed closely due to the risk of urticaria escalating to anaphylaxis, with particular attention paid to the patient's airway, breathing, and circulation (ABCs). Once a patient is deemed hemodynamically stable, a more detailed history and physical examination should be performed.

The history of present illness is a key part of diagnosing urticaria. Patients should be queried about the timing and onset of symptoms; any previous episodes of urticaria, asthma, allergies, or any other

atopic conditions; foods eaten; insect stings; and physical or environmental exposures. Urticaria may be delayed after exposure, so the history should cover the past 12 hours before the onset of symptoms. The history should also include a complete inventory of all medications taken by the patient, paying particular attention to antibiotics and aspirin or other NSAIDs. Many patients will not consider OTC medications or supplements (vitamins, botanicals, etc.) to be significant and will neglect to mention them. Since many of these substances can elicit urticaria, it is very important to specifically inquire about them. It is also important to inquire about recent travel, as this may provide clues about potential infections and parasites.

The physical examination should include a thorough skin examination with the patient undressed, noting any other skin conditions. All urticarial lesions should be described in detail as to size, shape, pattern, color, and temperature. The distribution of wheals may provide clues to the etiology of the condition since physical urticaria may be localized to skin sites exposed to vibrations, pressure, latex, cold, sun, or water. Particular importance should also be placed on looking for signs of insect bites or stings. The face and extremities should be inspected for signs of angioedema, which can present concurrently with urticaria. A thorough pulmonary examination should also be performed as respiratory complications such as wheezing, shortness of breath, and airway compromise may occur with urticaria. Particularly, if deep cutaneous edema is noted, the physician must ensure that the airway is patent and uninvolved. A thorough physical examination should also look for signs of infection or other systemic conditions as potential causes.

In a majority of cases, a precise underlying cause of urticaria will not be identified (1). Beyond a good history and physical examination, extensive evaluation in the ED is not indicated. However, simple maneuvers, such as placing an ice cube on the forearm (cold urticaria), immersing a hand in warm water (cholinergic urticaria), or “writing” on the skin (dermatographism),

may be performed in an attempt to elicit symptoms if the clinical history is suggestive.

ED MANAGEMENT

In the emergency room, the primary therapeutic intervention to treat urticaria has been directed at relief of pruritus. The most immediate concern is that all potentially offending agents and exposures should be eliminated to reduce progression of the rash and clinical symptoms. The mainstay of treatment for urticaria (Table 174.3) is antihistamines, though steroids may be considered in severe cases, especially when angioedema is present. Urticaria that progresses to anaphylaxis is treated with epinephrine (see Chapter 175).

TABLE 174.3
Treatment of Urticaria

Class	Medication	Adult Dosing	Pediatric Dosing	Considerations
H_1 blockers				
1st generation	Diphenhydramine (Benadryl)	25–50 mg PO/IM/IV q6h	1 mg/kg PO q6h	Sedating, avoid with concurrent monoamine oxidase inhibitors (MAOIs) pregnancy category B
	Hydroxyzine (Vistaril)	25–100 mg PO/IM qid	0.5–1 mg/kg/dose IM q4–6h 2 mg/kg/d PO divided tid	Sedating, cannot be given IV pregnancy category B
	Cyproheptadine (Periactin)	4 mg PO tid	0.25 mg/kg/d divided tid	Sedating, pregnancy category B
	Chlorpheniramine (Chlortrimeton)	4 mg PO q4h		Sedating, pregnancy category B
2nd generation	Cetirizine (Zyrtec)	5–10 mg PO qd	2–5-yr-old: 2.5 mg PO bid	Less sedating than 1st generation, available in chewable tablets pregnancy category B
	Fexofenadine (Allegra)	60 mg PO bid	6–11-yr-old: 30 mg PO bid	Nonsedating pregnancy category C
	Loratadine (Claritin)	10 mg PO daily	<2–yr-old: not established 2–5-yr-old: 5 mg PO qd	Nonsedating pregnancy category B
Corticosteroids	Prednisone	40–60 mg PO qd for 3–5 d; no taper required	1–2 mg/kg/d divided bid	Caution in diabetics pregnancy category D
	Methylprednisolone (Solu-Medrol)	125 mg IV/IM	0.5–2 mg/kg/d IV/IM/PO (max: 125 mg)	Caution in diabetics pregnancy category D
	Hydrocortisone	15–240 mg IV bid 0.5–2.5% topical qd or bid	1–5 mg/kg/d IV (max: 500 mg)	Caution in diabetics pregnancy category D PUPPP only pregnancy category C

H_1 Receptor Antagonists (Antihistamines)

Antihistamines reduce symptoms by binding to H_1 receptors in the blood vessels and histamine-selective (itch-specific) C nerve fibers, reducing permeability and irritability, respectively. They do not prevent mast cell degranulation. The antihistamines are divided into two generations. First-generation drugs (e.g., diphenhydramine, chlorpheniramine) distribute readily into the CNS and are relatively nonspecific for H_1 receptors, having antimuscarinic, anti-serotonin,

and anti–α-adrenergic activity. This leads to a wide variety of adverse effects, most notably sedation. Second-generation drugs (e.g., loratadine, cetirizine, fexofenadine) are much more highly specific for H_1 receptors and are less lipid soluble, making them less capable of traversing the blood–brain barrier and dramatically reducing sedative and other CNS effects. Note that relief with any antihistamine may be incomplete as many additional vasoactive peptides can be released by mast cells.

Second-generation, nonsedating antihistamines are considered first-line treatment for urticaria (14–16). In controlled studies, these drugs have been shown to be more effective than first-generation antihistamines at reducing wheals and erythema (17), and they have few adverse side effects, making them safer and raising patient compliance. Dosing should begin at the usual therapeutic dose and, if ineffective, can be increased until four times the normal therapeutic dose has been administered. Evidence of the effectiveness of higher doses is mixed, but appears safe and is worth consideration. First-generation drugs can also be used, but have a markedly increased adverse effect profile, including tachycardia, constipation, urinary retention, dizziness, and orthostatic hypotension. The first-generation drug diphenhydramine does have the advantage of potential IV administration for faster relief of symptoms (oral administration of all antihistamines can take 1 to 2 hours to reach peak blood concentration).

Solar urticaria and delayed pressure urticaria have both been shown to be refractory to antihistamine treatment (18). In both cases, antihistamines should be attempted, however. Solar urticaria that is resistant to antihistamines is usually treated with phototherapy and/or plasmapheresis, neither of which are useful in the ED (11). Fortunately, the condition clears in a few hours after removal from the triggering light source. Few effective options exist for delayed pressure urticaria that does not respond to antihistamines, aside from high-dose corticosteroids (10). PUPPP is not relieved with antihistamines and is instead treated with topical corticosteroids.

Steroids

Corticosteroids are not normally used to treat mild, uncomplicated urticaria (14–16), but may be useful in severe cases, especially when angioedema or respiratory complications exist. When used, a short, 3- to 5-day course with no taper is all that is required.

Epinephrine

Epinephrine is the first-line treatment in the setting of urticaria accompanied by anaphylaxis. Epinephrine may be administered intravenously (1 mL of 1:10,000 solution over several minutes, repeated every 5 to 15 minutes as necessary or followed by a drip of 1 to 4 μg/min). Epinephrine can be also given intramuscularly (0.3 to 0.5 mL of 1:1,000 solution every 3 to 5 minutes). After first-line therapy has been started, antihistamines, corticosteroids, and intravenous fluids should be administered. Bronchodilators may also be given as deemed necessary.

Other

Several studies have investigated the use of H_2 receptor antagonists (e.g., famotidine, cimetidine), both as monotherapy and in combination with H_1 receptor antagonists. However, a recent Cochrane review concluded that the evidence was insufficient to make a recommendation as to their use (19). Recent literature also shows little evidence for the effectiveness of leukotriene receptor antagonists (e.g., montelukast) in treating most forms of urticaria (20). Although potentially useful in the management of some forms of chronic urticaria, they have little place in the ED. Many other drugs have been investigated for efficacy in treating urticaria, with mixed results, though there is not enough evidence to recommend their routine use in the ED at this time (14–16).

One final interesting development is that soaps with a higher pH can significantly irritate and weaken the skin, which could either provide an entry route for allergens or exacerbate existing urticaria (21). It may be useful to advise patients with chronic idiopathic urticaria to test the pH of their soap (pH paper can be purchased

online) and to switch brands if it is higher than pH 6.5, which is the normal upper boundary of the skin's pH.

Special Considerations

Solid data are lacking concerning the use of antihistamines in pregnancy, though most are recognized as safe. The majority of antihistamines are listed as pregnancy category B, though a few (e.g., fexofenadine, desloratadine) are category C and should be used with caution or avoided in pregnancy. All antihistamines cross into the placenta and can be found in very small amounts in breast milk (<0.1% of maternal dose). First-generation drugs should be avoided immediately before parturition as this can cause respiratory depression and seizures in the neonate. Systemic corticosteroids are pregnancy category D and should only be used in life-threatening situations. Low-dose topical corticosteroids are pregnancy category C and can be used with caution in PUPPP.

Second-generation antihistamines are recommended for treatment of urticaria in pediatric populations due to their increased safety profile (22). In infants and young children, first-generation antihistamines can additionally cause a paradoxical central nervous system stimulation. Care must also be taken to ensure that pruritus is well controlled so as to prevent excessive scratching and subsequent infection. In addition, it is important to review underlying etiologies and exposure risks that are more specific to young children and infants.

Elderly patients are more vulnerable to adverse effects of first-generation antihistamines such as cognitive decline, delirium, inattention, and altered consciousness due to penetration of the blood–brain barrier. This is particularly problematic in patients with underlying dementia. Special consideration should also be given to elderly diabetic patients who may need to have their insulin dose altered to compensate for the predictable increase in blood glucose during steroid therapy.

CRITICAL INTERVENTIONS

- Administer epinephrine, antihistamines, and steroids for life-threatening urticaria accompanied by cardiovascular collapse, laryngeal edema, or bronchospasm.
- Second-generation antihistamines are the first-line therapy in the treatment of most uncomplicated urticaria without respiratory involvement.

DISPOSITION

Most acute urticaria begins to respond to treatment within 2 hours. Patients should generally be observed for at least this period of time or until definitive improvement is documented. Only patients with anaphylaxis, signs of airway compromise, or hemodynamic instability (hypotension) require admission. Persistent urticaria that fails to improve with antihistamine therapy should prompt further investigation. Urticaria with respiratory complications warrants prescribing injectable epinephrine. All patients should be advised that alcohol, aspirin, and NSAIDs can worsen symptoms. Antihistamines and steroids, if necessary, should be continued on an outpatient basis. Patients should be given instructions to return to the ED if a significant delayed reaction develops. Follow-up with an allergist may be advisable with severe or recurrent symptoms.

Common Pitfalls

- Patients should be carefully monitored. Urticaria may be the first sign of serious angioedema or anaphylaxis.
- First-generation H_1 receptor antagonists can cause side effects that include dry mouth, diplopia, blurred vision, tachycardia, constipation, and urinary retention. Sedation may also be prominent and may hinder performance at school or at work.
- Urticarial skin lesions may be the first manifestation of infection, parasitic infestation, or systemic diseases such as systemic lupus erythematous or urticarial vasculitis.
- Extensive laboratory workups in the ED are usually unnecessary and should be discouraged. A thorough history and physical examination are typically all that is needed.

SECTION XVIII
Allergic and Immunologic Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 175

Anaphylaxis

David N. Zull

Anaphylaxis is an acute, life-threatening condition; immediate recognition and treatment are critical. Manifestations may range from minor symptoms such as rash or lip swelling to sudden death from upper airway obstruction or shock. Even the patient who presents with urticaria alone can subsequently develop hypotension, bronchospasm, or laryngeal edema and should thus be treated with the same urgency as the patient with the full-blown anaphylactic syndrome.

The constellation of anaphylactic symptoms results from massive release of chemical mediators from mast cells and basophils throughout the body. For anaphylaxis to occur there must have been previous sensitization to a foreign substance, against which immunoglobulin E (IgE) was made by antibody-producing B lymphocytes. IgE binds to mast cells and basophils. On re-exposure to the foreign substance, antigen binds to the IgE on mast cells, which triggers massive release of chemical mediators from these cells. Anaphylaxis may also occur by mechanisms independent of IgE (formerly referred to as anaphylactoid reactions), including direct stimulation of mast cells and basophils or via activation of the complement cascade or the coagulation system (1–3).

Mediators released from activated mast cells include histamine, leukotrienes, prostaglandins, platelet-activating factor, tryptase, and cytokines. These mediators lead to an abrupt increase in vascular permeability and vasodilation, thereby resulting in hypotension, urticaria, and angioedema of the skin, upper airway, and gastrointestinal tract. Leukotrienes are potent bronchoconstrictors as

well. In life-threatening anaphylaxis, concomitant activation of complement, coagulation pathways, and the kallikrein–kinin system may contribute as well (2,3).

It is estimated that 1% to 3% of the population are at risk for anaphylaxis during their lifetime and that 1% of these episodes will be fatal, resulting in 1,000 to 1,500 anaphylactic deaths per year in the United States (4). Penicillin is the most feared cause of anaphylaxis, accounting for up to 75% of fatal drug reactions. More than 5% of the population report sensitivity to penicillin, yet more than 90% of these patients are skin-test negative and will not react. Penicillin allergy is generally manifested by urticaria alone or a delayed maculopapular drug eruption, but an estimated 25 of 100,000 patients treated with penicillin experience an anaphylactic reaction, and one will die. There is cross-reactivity among all penicillin derivatives including amoxicillin, dicloxacillin, piperacillin, and ampicillin. First- and second-generation cephalosporins demonstrate cross-reactivity in 2% to 3% of penicillin-allergic patients (documented by a positive penicillin skin test). Patients with reported penicillin allergy who are skin-test negative have less than a 1% cross-reaction rate.

Reactions to third- and fourth-generation cephalosporins appear negligible but these agents should still be used with caution if there is a history of life-threatening anaphylaxis. The cephalosporin-allergic patient will react to other cephalosporins and the penicillins, ampicillin and amoxicillin. Penicillin- and cephalosporin-allergic patients do not react to the monobactam, aztreonam, except for those allergic to ceftazidine. The safety of imipenem in the penicillin-allergic patient parallels the penicillin–cephalosporin risk profile, while the risk with meropenem and ertapenem is negligible (5,6).

Systemic allergic reactions to Hymenoptera stings are estimated to occur in about 1% of children and 3% of adults, and they account for approximately 40 to 100 anaphylactic deaths per year in the United States (7,8). Although 90% of stings are in children, 90% of fatalities to hymenoptera stings occur in adults, as children often manifest urticaria alone, adults present with hypotension or syncope. In emergency department (ED) series of anaphylaxis, hymenoptera

stings comprise 18% to 29% of cases (1,9–11). Yellow jackets, and to a lesser extent hornets, account for the majority of stings in the United States, especially in the late summer during dry spells. Honeybees are also a common culprit, with the Africanized form in the southern United States noteworthy for its aggressive pursuit and swarming behavior. Wasps, fire ants, harvester ants, and bumblebees are other stinging hymenoptera. Depending upon the severity of a systemic reaction, patients have a 15% to 75% risk of future reactions. In contrast, patients with large local reactions (>10 cm) are very low risk for systemic reactions on re-exposure. Secondary infection of hymenoptera stings is unusual, except when fire ant pseudopustules are unroofed. Kissing bugs in the Southwest are the most common nonhymenoptera insect whose bite can cause anaphylaxis. Bites and stings of other insects have been reported rarely to cause anaphylaxis; they include the horsefly, deerfly, blackfly, mosquito, caterpillar, centipede, and bedbug (7,8).

The administration of iodinated contrast media results in minor reactions like a transient rash in up to 2% of patients, but may exceed 4% in atopic or asthmatic patients and 7% in those with a history of prior contrast reactions. Anaphylaxis occurs in about 0.5% of IV iodinated contrast administrations, with 0.01% to 0.04% being life threatening. Contrast media reactions result from non-IgE mechanisms like direct mast cell degranulation or complement activation; thereby prior exposure is not required. Contrary to popular belief, there is no cross-reactivity in patients allergic to fish, shellfish, or topical iodine. There is no cross-reactivity of iodinated contrast with gadolinium, which has a reaction rate of less than 0.1% (12).

Foods are an increasingly recognized cause of fatal or near-fatal anaphylaxis and are the most common cause of anaphylaxis in outpatients, accounting for one-third of cases overall and for more than one-half of episodes in children. Peanuts, tree nuts, shellfish, milk, eggs, and wheat are most commonly implicated, but the latter three are limited to infants and toddlers. Shellfish predominates in adults, whereas nuts are the most common cause in older children. Peanuts and tree nuts account for more than 90% of fatalities (about

150 deaths per year in the United States), with highly allergic individuals reacting to the mere touch or smell of the food. Food-induced anaphylaxis manifests primarily with airway obstruction and rarely with hypotension. Gastrointestinal involvement is much more common in food reactions (40%) compared to other causes of anaphylaxis (4%) (13,14). Noteworthy is the presentation of anaphylaxis and abdominal pain subsequent to the ingestion of sushi, attributed to allergy to the Anisakis worm that may parasitize raw fish. Exercise and medications (NSAIDs) appear to have a facilitating effect in some food reactions (15). Oral allergy syndrome occurs in patients with a history of tree and weed pollen allergy in which there is sudden burning in the mouth and throat after ingestion of fresh fruit, nuts, or vegetables, followed by mild angioedema and sometimes modest systemic allergic symptoms.

NSAIDs are the most common medications causing anaphylaxis in the outpatient setting, often unrecognized due to their frequent use and over-the-counter availability (16). NSAIDs may also precipitate asthma exacerbations in over 5% of asthmatics and in the majority of patients with asthma and nasal polyps. NSAIDs also cause flares in patients with chronic urticaria and may facilitate anaphylaxis to other allergens.. Aspirin and all NSAIDs should be assumed to cross-react unless the patient has a clear history of tolerance to other NSAIDs; more than half of reactions are to a single NSAID. If an NSAID is required, COX-2 inhibitors (celecoxib, meloxicam) and nonacetylated salicylates (salsalate, diflunisal) can be used safely. For analgesia, acetaminophen in doses no more than 650 mg is the safest option (17).

Various parenteral therapeutic agents have been associated with anaphylaxis. After repeated administration, monoclonal antibodies like infliximab, or chemotherapeutic agents like platinum compounds, taxanes, and L-aspariginase, can result in acute allergic reactions (18). About 5% of patients administered alteplase (tPA) for ischemic stroke develop orolingual angioedema without other manifestations of anaphylaxis (19).

Exercise-induced anaphylaxis is usually associated with prior food or drug (NSAID) ingestion, but it can occur independently as well.

Episodes are more common and severe during weather temperature extremes, after alcohol, and during prolonged exertion, yet many patients find that there is no reproducible pattern and most patients have exercised for years before experiencing their first episode. Wheat is the most commonly implicated food, followed by shellfish, fruits, and vegetables (15). Cold exposure itself can precipitate urticaria and sometimes anaphylaxis in patients who have cold urticaria, an inherited disorder. Perioperative anaphylaxis is usually related to paralytic agents or latex and is manifested by circulatory collapse with a paucity of skin findings. Exposure to human proteins such as blood products, insulin, or seminal fluid may rarely result in anaphylaxis. Many agents have a histamine-releasing effect, resulting in diffuse flushing but rarely anaphylaxis; these include opiates, thiamine, vitamin K, and vancomycin (20). Idiopathic anaphylaxis accounts for up to one-third of cases in various series and is notable for rapid-onset and recurrent, unpredictable episodes, often requiring chronic antihistamines and steroids to achieve remission Table 175.1 (21) summarizes etiologic factors in anaphylaxis.

TABLE 175.1
Etiologic Agents in Anaphylaxis

IgE-Mediated Proteins

Venoms: hymenoptera (e.g., yellow jacket, hornet, wasp, honey bee, fire ant), kissing bug, biting flies, rattlesnake, jellyfish (8)

Foods: peanuts, tree nuts, shellfish, grains, milk, eggs, wheat (13,14)

Aeroallergens: allergy extracts, contaminated food

Biologics: infliximab, etanercept, adalimumab

Enzymes: streptokinase, chymopapain

Human proteins: insulin, ACTH, seminal fluid

Equine antisera: botulinum toxin, snake antivenom (rare with Fab fragments)

Vaccines: influenza, MMR, yellow fever (egg), tetanus

Miscellaneous: latex, protamine

IgE-Mediated Haptens

Antibiotics: penicillins, cephalosporins, sulfonamides, fluoroquinolones, tetracyclines (18)

Chemotherapeutic agents: platinums, taxanes, L-aspariginase

Neuromuscular blockers: succinylcholine, rocuronium

Prostaglandin Inhibition

NSAIDs: aspirin (excluding nonacetylated salicylates), indomethacin, ibuprofen, naproxen, etc. (17)

Complement Activation

Blood products: gamma globulin, plasma, whole blood

Dialysis-related

Direct Mast Cell Degranulation

Drugs: opiates, vancomycin, thiopental

Vitamins: thiamine, vitamin K

Polysaccharides: dextrans

Radiocontrast media: ionic >> nonionic

Physical Factors

Exercise-induced anaphylaxis (15)

Food- or NSAID-related anaphylaxis unmasked by exercise

Cold-induced urticaria and anaphylaxis

Idiopathic (21)

Repeated intermittent exposure to a substance or drug increases the risk of sensitization; the more direct the route to the systemic circulation, the greater the likelihood and severity of a reaction. The possible routes of exposure in descending order of severity are

intravenous, intramuscular, subcutaneous, intradermal, inhalational, oral, other mucous membranes, and topical.

Symptoms of anaphylaxis usually begin <30 minutes after exposure and are often immediate. Antigens given orally may have a 2-hour delay before symptoms occur. In general, the more immediate the reaction, the more life-threatening it is. Symptoms may last only a few minutes, even without therapy but, on average, persist for 2 to 4 hours, with the exception of angioedema, which often persists beyond 24 hours. About 5% of patients with anaphylaxis experience a biphasic course, with recurrent anaphylaxis within 8 hours, despite earlier resolution. Delays in or inadequate use of epinephrine and steroids are often implicated in the recrudescence of symptoms (22).

CLINICAL PRESENTATION

Anaphylaxis is often heralded by premonitory symptoms (Table 175.2). Pruritus of the palms and soles, tingling about the mouth and tongue, generalized warmth, tightness in the chest, and a lump in the throat are commonly described. Dizziness or syncope secondary to hypotension may be presenting manifestations of anaphylaxis in the absence of any other signs or symptoms of allergic reaction.

TABLE 175.2
Symptoms and Signs of Anaphylaxis

Reaction	Symptom	Sign
Urticaria	Itching	Raised wheals diffusely, wandering, evanescent
Angioedema	Nonpruritic tingling	Swelling of lips, eyes, hands, uvula, tongue
Laryngeal edema	Hoarseness	Inspiratory stridor
	Dysphagia	Intercostal and clavicular retractions
	Lump in throat	
	Airway obstruction	Cyanosis
	Sudden death	
Bronchospasm	Cough, dyspnea, chest tightness	Wheezing, tachypnea, retractions
Hypotension	Dizziness	Hypotension (mild to severe)
	Syncope	
	Confusion	Tachycardia
	Oliguria	
Rhinitis	Nasal congestion	Mucosal edema
	Itching and fluid	
Conjunctivitis	Tearing	Lid edema, injection, chemosis
	Itching	
Gastroenteritis	Cramping	Normal examination
	Diarrhea	
	Vomiting	
Altered sensorium infants)	Irritability somnolence	Nonfocal neurologic examination
Gynecologic (pregnancy)	Vulvovaginal pruritis, uterine contractions, preterm labor	Mucosal edema & erythema

More than 90% of patients have urticaria or angioedema. Urticaria (edema of the upper dermis) appears as raised erythematous wheals in evanescent pruritic patches. Angioedema represents edema of the deep dermis and appears as puffy, nonpitting areas of skin or mucous membrane. Angioedema is generally painless and nonpruritic; patients note only tingling and swelling in the affected areas. It tends to be most prominent about the face and lips and less so on the hands and arms.

Laryngeal edema resulting in acute upper airway obstruction is the principal cause of death from anaphylaxis. The onset can be dramatic and may be mistaken for a sudden cardiac death or acute upper airway obstruction from a foreign body. Angioedema of the lips, uvula, tongue, and oropharynx is less likely to obstruct the airway but must be treated aggressively because of the likelihood of concomitant edema of the larynx. Uvular edema, in particular, is a

helpful marker for potential laryngeal involvement. Frequently, however, the patient complains of hoarseness and a lump in the throat, and the examination of the oropharynx is completely normal. Indirect laryngoscopy may reveal supraglottic or laryngeal edema, but this examination should not delay the prompt administration of epinephrine in a patient with these complaints.

Bronchospasm is common in the anaphylactic syndrome, but it tends to be mild unless the patient has a pre-existing history of asthma. Pulmonary edema, although reported in anaphylaxis, is generally considered a rare terminal event and not part of the syndrome.

Refractory hypotension is second only to laryngeal edema as a cause of death from anaphylaxis. A drop in blood pressure of 20 to 30 mm Hg is typical, but there is great variability. When sudden in onset, syncope or sudden death may occur.

Although it is usually overshadowed by other symptoms, abdominal cramping can occur in anaphylaxis, most notably in food-related episodes. Angioedema of the gut lining causes this colic as well as vomiting, diarrhea and, rarely, hematochezia. Rhinitis, nasal obstruction, chemosis, and conjunctivitis are other common manifestations of mucous membrane involvement, but they are not life threatening Acute coronary syndrome, takotsubo cardiomyopathy, and ventricular tachycardia have been reported, and nonspecific ST-T wave changes are commonly seen on the electrocardiogram in patients suffering from anaphylaxis. These cardiac manifestations are generally attributed to hypotension, hypoxia, and overzealous epinephrine therapy, although histamine and cytokines may induce coronary vasospasm and cardiac dysrhythmias (20).

Unique manifestations of anaphylaxis may be seen in specific patient subgroups. In pregnancy, vulvar and vaginal itching, low back pain, uterine cramping and preterm labor are described (23). In infants, neurologic presentations may predominate, with irritability, persistent crying, and somnolence (1,24,25).

DIFFERENTIAL DIAGNOSIS

The diagnosis of anaphylaxis is often obvious when antigen exposure is rapidly followed by urticaria, angioedema, bronchospasm, upper airway edema, and hypotension. Confusion in the diagnosis may occur when a delay in the development of symptoms obscures a cause-and-effect relation or when the syndrome is only partially expressed. Differentiating acute, severe urticaria, for example, from anaphylaxis is a moot point. The greatest confusion may arise when anaphylaxis presents as isolated hypotension; it should, therefore, be considered in the differential diagnosis of syncope and vascular collapse.

The acute development of isolated angioedema of the skin and upper airway is a common presentation of anaphylaxis, but it may also be due to hereditary angioedema (HA). This rare, autosomal dominant disease is characterized by the absence of a functional C1 inhibitor, allowing free activation of the complement cascade. HA is characterized by repeated episodes of angioedema of the skin (hands, feet, genitalia), upper airway, and gut. Episodes generally date from adolescence, clustering in the 11- to 45-year age range (26,27).

Attacks of HA may be precipitated by minor trauma, stress, and medications (estrogens, angiotensin-converting enzyme inhibitors [ACEIs]), but most occur without an external trigger. Vomiting and severe colicky abdominal pain is common and can mimic an acute abdomen or progress to small bowel obstruction from mucosal edema. Both urticaria and hypotension are absent in HA. Laryngeal edema can cause acute airway obstruction and death, but usually the progression is gradual, peaking in 8 hours. Typically, the edema will plateau for 24 hours, followed by gradual resolution over the next 2 days A reduction in the C4 level during an attack is diagnostic. Although it is routine to administer epinephrine, antihistamines, and steroids to patients with anaphylactic angioedema, these are generally ineffective in the hereditary disorder. C1 inhibitor concentrate is the most effective treatment in HA patients with airway compromise, providing relief of symptoms within 30 to 60 minutes. Fresh frozen plasma is an effective substitute, and it does not appear to exacerbate symptoms as was once suspected. Icatibant, a bradykinin receptor antagonist, or ecallantide, a kallikrein

inhibitor, administered subcutaneously has shown efficacy as well (26,27).

Rapid development of edema of the upper airway may also result from viral or bacterial infection. However, pain, fever, and findings of erythema and exudate are not present in anaphylaxis. Airway compromise may occur in Stevens–Johnson syndrome and toxic epidermal necrolysis, but mucosal sloughing and bleeding distinguish them from anaphylaxis.

ACEIs produce cough in 10% to 20% of patients and life-threatening tongue and palatal angioedema in 0.1% to 0.7%. African Americans account for 70% to 90% of cases, with smoking, increasing age, and female gender further increasing the risk. Although the appearance is indistinguishable from anaphylactic swelling, the development is more gradual, and other features of anaphylaxis are absent. Patients may have been taking ACEIs for up to 10 years before an initial episode; the mean is 2 years, and about one-fourth of episodes occur within the first month of treatment. Angiotensin receptor blockers may be substituted for ACEIs, but similar angioedema has been described. ACEI-associated angioedema may be resistant to standard therapy but responds to fresh frozen plasma and bradykinin–kallikrein antagonists similar to HA (28,29).

Rarely, patients may experience stridor and obstructive airway symptoms secondary to vocal cord dysfunction or as a manifestation of hysteria; indirect laryngoscopy is the only means to verify these suspicions.

Scombroid fish poisoning may mimic anaphylaxis, presenting with acute urticaria, flushing, peppery taste in the mouth, vomiting, diarrhea, abdominal cramps, headache, and dysphagia. This syndrome occurs shortly after eating fish with a high histidine content (such as tuna or mahi-mahi) for which there has been a breach in the refrigeration process sometime between the catch and consumption, leading to bacterial breakdown of histidine to histamine. A clustering of cases of apparent anaphylaxis is often the clue to this entity (30).

Transient flushing seen in monosodium glutamate reactions may be confused with anaphylaxis, but the prominence of headache and

numbness or tingling distinguishes it from an allergic reaction.

Systemic mastocytosis and the carcinoid syndrome may present with intense flushing and hypotension, mimicking anaphylaxis; prominent gastrointestinal symptoms, hepatomegaly, and provocation by alcohol help distinguish these entities. There has been increased recognition of mastocytosis in patients with idiopathic anaphylaxis. An elevated tryptase level between attacks is suggestive (21).

The systemic capillary leak syndrome is a rare disorder characterized by life-threatening episodes of hypovolemic shock, often accompanied by truncal and extremity swelling. Transient polycythemia and hypoalbuminemia during attacks are pathognomonic; the presence of a monoclonal gammopathy may provide a clue to the diagnosis between attacks.

Laboratory confirmation of anaphylaxis is problematic and rarely required. Plasma histamine rises transiently but normalizes within 60 minutes from onset. Serum tryptase peaks at 60 to 90 minutes from onset and may remain elevated for up to 5 hours, but it is less sensitive.

ED EVALUATION AND MANAGEMENT

Evaluation of the upper airway and careful blood pressure monitoring are the immediate priorities in the care of the patient with possible anaphylaxis. Angioedema of the lips, tongue, uvula, and soft palate, as well as symptoms of hoarseness, stridor, dysphagia, or lump in the throat should alert the physician to progressive airway compromise. Such patients are treated immediately with epinephrine 0.3 to 0.5 mL (1:1,000 dilution) IM (0.01 mL/kg in children to a maximum of 0.3 mL). For both children and adults, the IM route is preferred, as it has been demonstrated to have a faster onset and significantly higher blood levels than the subcutaneous route. The lateral thigh is the preferred injection site, demonstrating superior bioavailability compared to the deltoid region. The dose can be repeated at 5- to 15-minute intervals, to a maximum of 1 mg of epinephrine. β-adrenergic stimulation promotes the synthesis of cyclic AMP in mast cells, which blocks further

release of chemical mediators. Epinephrine also exerts a therapeutic benefit by its α-adrenergic effect, causing vasoconstriction, which results in an improvement in blood pressure and a decrease in swelling of edematous tissues (2,3).

The patient is placed on a cardiac monitor and given oxygen by cannula, and an intravenous line of normal saline is established. If hypotension is present, saline should be infused wide open until the blood pressure responds (typically 1 to 2 L in an adult or 1 or 2 20-mL/kg boluses in a child). If hypotension persists or is profound from the outset, or if airway obstruction appears imminent, intravenous epinephrine may be administered. The most common error made in this situation is to give too much epinephrine too fast, precipitating cardiac dysrhythmias or chest pain. An aggressive approach would include the administration of 1 mL of 1:10,000 epinephrine diluted in 10 mL of normal saline and given as a slow IV push over 3 to 5 minutes (20 to 33 μg/min to 100 μg total). If life-threatening symptoms persist, this bolus can be repeated (31). A more conservative consensus approach recommends the preparation of a drip consisting of 1 mL (1 mg) of a 1:1,000 dilution of epinephrine in 250 mL of D5W infused at 1 to 10 μg/min (0.014 to 0.14 μg/kg/min) If cardiac arrest occurs in anaphylaxis, the epinephrine protocols above are not adequate treatment, and the dose should be escalated to 1 to 3 mg over 3 minutes (2,3).

Massive angioedema may preclude orotracheal intubation, such that cricothyroidotomy may have to be performed. Aerosolized epinephrine (racemic 2.25% solution, 0.5 mL in 3.5 mL saline; or levo-epinephrine 1:1,000, 5 mL) may decrease supraglottic and laryngeal edema, buying time while preparations are made to establish an airway and parenteral epinephrine can be administered. In addition, heliox decreases airflow resistance and improves ventilation in upper airway obstruction, providing a very valuable temporizing measure. If IV access is unavailable, sublingual or intraosseous injection or endotracheal administration of epinephrine is considered. If improvement in blood pressure and airway obstruction are incomplete, epinephrine can be continued 0.3 mL IM at 20-minute intervals or by an epinephrine drip (1 to 10 μg/min).

Hypotension generally responds to one or two IM doses of epinephrine and rapid saline infusion. It is important that the hypotensive patient be kept supine or in Trendelenburg position if the airway is not compromised, as they are exquisitely sensitive to preload, and assumption of an upright posture can lead to a precipitous drop in cardiac output and subsequent arrest, referred to as the empty heart syndrome. If hypotension persists, virtually all patients will respond to IV epinephrine. Patients who are refractory to IV epinephrine may respond to methylene blue, an inhibitor of nitric oxide production, given as an IV bolus of 1.5 to 2 mg/kg (32). Most patients with anaphylaxis do not require such intensive therapy, however. In general, one or two doses of epinephrine subcutaneously at 15- to 20-minute intervals and 1 L of saline IV are adequate. Patients with acute, severe urticaria alone may benefit from a single dose of epinephrine, yet it is usually not necessary because there is no life threat. Bronchospasm in anaphylaxis is responsive to epinephrine alone, but in patients with pre-existing asthma, repeated albuterol nebulizations may be necessary (2,3).

Corticosteroids are recommended in all patients with anaphylaxis. Although there is no immediate benefit to their administration, steroids speed the resolution of angioedema and urticaria and are thought to prevent a biphasic course in anaphylaxis (22). Dosage recommendations are similar to those for status asthmaticus: methylprednisolone (Solu-Medrol), 125-mg intravenous push, followed by 60 mg every 4 to 6 hours in patients whose symptoms persist despite standard therapy. Milder episodes are often treated with oral prednisone 40 to 60 mg initially.

Steroids have an important role in prophylaxis of anaphylaxis in patients allergic to iodinated radiocontrast material requiring IV contrast. The most common regimen is prednisone 40 mg orally at 13, 6, and 1 hour prior to administration of contrast (2,3). Although strong clinical evidence is lacking, consensus opinion suggests that all patients with anaphylaxis should receive an antihistamine such as diphenhydramine (Benadryl), 25 to 50 mg, to a maximum of 100 mg if needed. The route of administration depends on the severity of the reaction. Although less effective for pruritus, H_2 blockers (famotidine

20 mg or ranitidine 50 mg IV push) appear equivalent to H_1 blockers in urticaria and anaphylaxis, and they may offer an advantage if sedation and anticholinergic side-effects are undesirable. The combination of H_1- and H_2 blockers are superior to either agent alone, especially in severe anaphylaxis (33). The addition of fexofenadine (Allegra) or cetirizine (Zyrtec) orally allows more complete histamine blockade without associated sedation or anticholinergic effects and is safe when added to traditional antihistamines. Antihistamines should not be relied upon as the sole treatment in anaphylaxis, except perhaps in the most mild, self-limited of cases.

Preventing further exposure to the antigen is critical; for instance, a tourniquet can be placed above an injection site, the stinger of a honey bee can be removed, offending chemicals can be washed off, and even charcoal can be considered.

Throughout therapy, the vital signs are reassessed frequently, and the airway is checked for edema of the uvula or oropharynx. The patient is asked about symptoms of laryngeal edema or bronchospasm and examined for signs of stridor, retractions, or wheezing. These assessments are made at 1- or 2-minute intervals at first, with the intervals lengthened as the patient stabilizes.

For patients older than age 60 or those with a cardiac history, saline is given cautiously for hypotension while monitoring closely for volume overload. Epinephrine should not be withheld in patients with potential upper airway obstruction or in those with hypotension unresponsive to volume loading. A test dose of epinephrine, 0.15 mL (1:1,000) IM can generally be given safely. If no chest pain or cardiac dysrhythmias develop, another test dose or a full dose is then given. IV epinephrine should be avoided in these patients unless death appears imminent without its use, but limiting the infusion to 1 to 4 μg/min. Pre-existing medications which the patient is taking may aggravate an episode of anaphylaxis or make the patient unresponsive to therapy. Most noteworthy is the patient on a β-adrenergic blocker, which may exacerbate bronchospasm as well as limit the efficacy of epinephrine, leading to a net α-adrenergic effect. In this situation, glucagon, 1 to 2 mg given IV over 5 minutes may be

of great benefit, repeating the dose up to 5 mg total if needed, followed by an infusion of 5 to 15 μg/min titrated to response (18). Terbutaline, 0.25 mg subcutaneously, may also be considered. ACEIs have also been reported to aggravate hypotension and angioedema in anaphylaxis, necessitating more aggressive management Table 175.3 (2,34) summarizes treatment guidelines for anaphylaxis.

TABLE 175.3
Treatment of Anaphylaxis

1. Remove antigen, delay absorption.
2. Maintain an adequate airway and keep supine if airway will allow.
3. Epinephrine
   - 0.3 mL SC 1:1,000; given IM in the lateral thigh, repeat at 5- to 15-min intervals.
   - If severe may increase dose to 0.5 mL.
   - If shock or incipient airway obstruction, give 1 mL of 1:10,000 dilution diluted further in 5–10 mL saline slow IV over 3–5 min, repeating as indicated by clinical response.
   - If protracted severe symptoms, start a drip: 1 mg in 250 mL DSW, 1–10 µg/min.
   - If patient is >60 yr old or has a cardiac history and life-threatening symptoms exist, give a test dose of 0.15 mL IM (1:1,000). If shock resistant to other measures or imminent airway closure, consider a drip as above.
   - If cardiac arrest occurs, give 1 mg IV over 1–3 min. Repeat if no response.
4. Volume expansion with normal saline or lactated ringer
   - Shock: 1 L over 15 min, then repeat 1 or 2 more times if needed
5. Antihistamines
   - Diphenhydramine: 25–50-mg IM or IV push. May repeat within 15 min to a maximum of 100 mg, then smaller doses q2–4h as needed.
   - H2 blocker: Famotidine 20 mg or ranitidine 50 mg IV push repeated at 6-h intervals as needed; given as an adjunct to diphenhydramine if refractory to treatment or if sedation and anticholinergic effects are a problem.
6. Methylprednisolone
   - 125-mg IV push; may repeat 60 mg q4h if persistent symptoms.
7. If resistant hypotension:
   - Continue aggressive fluid resuscitation
   - Trendelenburg position
   - Epinephrine infusion titrated to toxicity
   - Methylene blue 1.5–2-mg/kg IV push (if refractory despite above measures) (32)
8. If imminent airway obstruction (stridor, drooling, hoarseness):
   - IV epinephrine as noted above
   - Nebulized racemic epinephrine (0.5 mL of 2.25% in 3.5-mL normal saline) or epinephrine (5 mL of 1:1,000 dilution)
   - Heliox by mask (70/30 or 80/20 with additional O_2 by nasal canula)
   - Prepare for intubation or cricothyrotomy
9. If resistant bronchospasm (usually pre-existent asthma):
   - Albuterol by nebulization (3–6 mL of 0.083% solution) ± ipratropium; repeat as needed.
10. If β-blocker–accentuated anaphylaxis: (34)
    - Glucagon 1 mg IV push over 4–5 min; repeat as needed up to 5 mg, then 5–15 µg/min drip
    - Terbutaline 0.25 mg subcutaneously every 15 min or isoproterenol drip
11. Outpatient regimen if stable for discharge:
    - Prednisone 40–60 mg/d for 3 d
    - Prescribe one or two antihistamines for 3 to 5 d (only one per class)
      - H_1 blocker (traditional)
        - Diphenhydramine 25–50 mg q6h prn
        - Hydroxyzine 25 mg q6h prn
      - H_1 blocker (nonsedating)
        - Cetirizine 10 mg/d
        - Fexofenadine 180 mg/d
      - H_2 blocker
        - Famotidine 40 mg/d
        - Ranitidine 300 mg/d
    - Prescribe EpiPen 2-Pak or an Auvi-Q autoinjector and refer to allergist if idiopathic or high risk of recurrence (food, bee sting)

Fatalities in anaphylaxis may occur in up to 2% of cases. Foods are generally responsible in children to young adults, while medications and venoms are the etiology in older adults. Risk factors for fatality in anaphylaxis include asthma, delay in administration of epinephrine, cardiopulmonary disease, upright posture maintained during the attack, systemic mastocytosis, and other atopic diseases (4,11).

CRITICAL INTERVENTIONS

- Administer epinephrine intramuscularly immediately for patients presenting with hypotension or acute angioedema of the lips, tongue, uvula, and soft palate.
- Administer epinephrine slow IV push or via infusion pump if there is imminent airway compromise, profound hypotension, or progression of symptoms despite IM epinephrine.
- In addition to IV epinephrine, treat supraglottic and laryngeal edema with aerosolized epinephrine while preparing to establish an airway.
- Hypotension should be treated with aggressive fluid resuscitation as well as maintaining the patient supine or in Tredelenburg position to enhance preload.
- Administer corticosteroids and antihistamines (H_1 and H_2) to all patients with anaphylaxis.

DISPOSITION

If all symptoms of anaphylaxis resolve rapidly and completely with initial therapy, the patient can be observed in the ED without further treatment. If symptoms do not recur in the next 2 to 4 hours, the patient may safely be discharged and should continue on a 3-day course of prednisone (40 mg/d) or a single dose of dexamethasone (10 to 20 mg) and a long acting antihistamine, such as fexofenadine (180 mg/d), cetirizine (10 mg/d), or famotidine (40 mg/d), saving diphenhydramine 25 mg as rescue therapy for pruritis or rash. An epinephrine autoinjector, such as EpiPen or Auvi-Q) should be prescribed for patients with food-related, Hymenoptera, and

idiopathic anaphylaxis. Both the EpiPen 2-Pak and the Auvi-Q contain two doses of epinephrine as well as a training device. Discharge instructions should caution the patient to avoid any suspected inciting cause such as medications, foods, chemicals, or even exercise. The patient should be instructed to return to the ED immediately if hoarseness, dysphagia, wheezing, dyspnea, dizziness, or worsening rash with swelling develops. Follow-up with an allergist should be recommended, particularly if no obvious etiology has been identified in the ED or if desensitization is indicated.

Patients who had a life-threatening manifestation on presentation (shock or upper airway obstruction), even if it resolved with acute therapy, should be admitted. Those who had a slow or incomplete response to therapy or any worsening of symptoms during ED evaluation and treatment also require admission, as do elderly or debilitated patients or those with serious underlying cardiac disease. If hypotension or significant airway compromise persists, admission to an ICU is mandatory. For most of the remaining patients, a 12- to 24-hour observation period is indicated (10).

Because anaphylaxis can progress in such a fulminant manner, transfer to another institution is not recommended unless prolonged observation in the ED has shown the patient to be stable.

Common Pitfalls

- Giving epinephrine undiluted and too rapidly when intravenous administration is required (31).
- Withholding epinephrine therapy in the elderly or cardiac patient with imminent airway obstruction or refractory shock.
- Not recognizing the possibility of recrudescence of symptoms 4 to 8 hours after an initial complete response to therapy (22).
- Not identifying common etiologies of anaphylaxis, including over-the-counter NSAIDs, foods (shellfish, nuts), antibiotics (despite the lack of previous reactions and regardless of duration of therapy), antihypertensive drugs (β-blockers, ACEIs), and exercise.
- Not treating upper airway symptoms such as hoarseness, foreign body sensation, and dysphagia, with prompt administration of IM

epinephrine.
- Not recognizing uvular and pharyngeal angioedema as warning signs of laryngeal involvement.
- Relying solely on epinephrine, antihistamines, and steroids in patients suspected of having HA or ACEI angioedema, and not considering the use of fresh frozen plasma, icatibant, ecallantide, or C1 inhibitor concentrate.
- Failing to recognize that anaphylaxis can present with shock or acute airway obstruction alone, without any other manifestations of the classic anaphylactic syndrome.
- Failing to prescribe EpiPen or Auvi-Q and to provide allergy referral to patients with idiopathic anaphylaxis and those at high risk for recurrent episodes.

CHAPTER 176

Angioedema

Bella Liu and Eric R. Snoey

Angioedema is transient edema of deep dermal and subcutaneous tissues characteristically localized to the face, lips, intraoral, and throat structures (1,2). The potential for rapid, life-threatening airway compromise from laryngeal edema makes identification and prompt treatment of angioedema of special importance to emergency physicians (1).

Angioedema can be classified according to its most common etiologies:

- Allergic reactions to food, drug, or environmental triggers
- Use of angiotensin-converting enzyme inhibitors (ACEIs)
- Hereditary or acquired angioedema (HAE or AAE)
- Idiopathic causes (2,3).

These etiologies of angioedema can be further classified by their respective pathophysiology, which involve mainly two immunologic mechanisms (Table 176.1). In angioedema associated with allergic reactions, mast cell degranulation with histamine release is responsible (1,2). In cases associated with ACEIs, HAE, and AAE, the angioedema is mediated by the process of bradykinin formation (1,2,4). In addition, a significant number of cases of angioedema occur with no clear cause; numbers as high as 21% to 59% have been reported for idiopathic angioedema (3,5). The end result, regardless of the underlying etiology or mechanism, is an increased permeability of submucosal or subcutaneous capillaries and venules, resulting in fluid extravasation and subsequent edema (1).

TABLE 176.1
Causes of Angioedema

	Mechanism	Treatment Considerations
Allergic	IgE/mast cell/ histamine-mediated	Treatment consists of epinephrine, H_1- and H_2 blockers, and corticosteroids
ACEI-induced/ HAE/AAE	Bradykinin/C1 inhibitor-mediated	Treatment consists of fresh frozen plasma (FFP), C1 inhibitor concentrate, icatibant, or ecallantide. Epinephrine, H_1- and H_2 blockers, and corticosteroids are not effective, but should be trialed first in the emergency setting for angioedema of unclear etiology
Idiopathic	Unknown	Treat as angioedema of unclear etiology

Acute allergic angioedema is mediated by a type 1 hypersensitivity reaction involving allergen binding to IgE receptors on mast cells. The resulting degranulation and histamine release can produce both angioedema as well as more traditional manifestations of allergic reactions such as urticaria, bronchospasm, and even anaphylaxis (1,2). Typical triggers include foods, drugs, contrast dye, latex, environmental allergens, and insect stings (1). This histamine-mediated mechanism is also the common pathway for most drug-related angioedema, including angioedema caused by β-lactams, sulfonamides, opiates, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs), with the notable exception of ACEIs (1).

With approximately 40 million people taking ACEI medications worldwide, ACEI-associated angioedema is becoming an increasingly prevalent disease entity with an incidence approaching 2% according to some studies (2,6). African American patients have a four to five times greater incidence of angioedema; smoking, older age, and female sex are additional risk factors (6). The pathophysiology of ACEI-associated angioedema relates to angiotensin-converting enzyme's dual role in inhibiting both the renin–angiotensin pathway (thereby lowering blood pressure) and the degradation of bradykinin, a powerful vasodilator (2). The initial presentation of ACEI-associated angioedema is highest during

the first month of use, but about a third of cases present more than 6 months after initiation of ACEI therapy, sometimes up to several years (2,6).

Epidemiologic data regarding HAE and AAE are sparse; the incidence of HAE is reported to be between 1:50,000 and 1:100,000 persons, with AAE being even more rare (4). In both HAE and AAE, decreased C1 inhibitor activity results in upregulation of the kinin–kallikrein system, leading to increased bradykinin levels, mast cell degranulation, and vascular permeability (2). The pathophysiology of HAE is due to a genetic defect leading to decreased levels or function of the native C1 inhibitor or in some cases due to a mechanism involving estrogen (1,2,4). Features that suggest HAE include presentation at younger age, often in the first three decades of life, a positive family history, and recurrent attacks of otherwise unexplained angioedema or abdominal pain (2,4). A family history is not always present, however, due to *de novo* gene mutations and varying degrees of gene expression (2). Also, a history of attacks in setting of stress, trauma, or surgery, even minor surgery such as dental procedures, is suggestive of HAE (1,2). The pathophysiology of AAE is less understood, but is likely the result of either increased consumption of C1 inhibitor or an autoantibody binding to C1 inhibitor rendering it nonfunctional (1,2). The latter can occur in B-cell lymphoproliferative disorders including malignancies such as lymphoma and various autoimmune diseases (1,2). An additional feature that suggests AAE is presentation at greater age, often after the fourth decade of life (2,7).

In comparison to angioedema in adults, angioedema in the pediatric population is a rare and much less studied phenomenon (2). The allergic variant is the most common with frequent links to food and other environmental triggers (2). In one small study, angioedema was attributed to food in 40%, insect bites in 30%, upper respiratory infections in 20%, and antibiotic use in 10% of cases (8). Compared to adults, children with angioedema have better prognosis; most respond rapidly to treatment and are less likely to require airway intervention or intensive care unit (ICU) admissions (8).

CLINICAL PRESENTATION

Patients with angioedema characteristically present with complaints of swelling in:

- Face and lips
- Tongue, soft palate, and uvula
- Oropharynx and larynx
- Bowel walls manifesting as abdominal pain, nausea/vomiting, diarrhea, or ascites
- Distal extremities
- Genitals (1)

The typical time course of symptoms is onset within minutes to hours and resolution within one or several days. On physical examination, the edema is nonpitting, nonpruritic, usually does not involve gravitationally dependent areas, and can be painful owing to distension and swelling of the skin (2). Up to 15% of patients with angioedema will develop some degree of airway obstruction (2). Important clinical clues that suggest airway involvement include:

- Dyspnea and respiratory distress
- Voice change
- Hoarseness
- Stridor
- Dysphagia
- Drooling (9,10).

Also, urticaria, bronchospasm, or even anaphylaxis may present if the angioedema is allergic in nature. Abdominal wall involvement leading to abdominal complaints such as pain, nausea or vomiting, diarrhea, and ascites are a less recognized manifestation of angioedema and may be a diagnostic challenge for emergency physicians (2,4,8). They can occur in isolation without the usual facial involvement, and at times the abdominal pain can be so severe that it is mistaken for an acute surgical abdomen (2).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of angioedema is broad (Table 176.2). In the ED, important common alternative diagnoses to consider include dependent edema (for example, due to congestive heart failure), acute abdominal pathology (for example, appendicitis), and infections (for example, cellulitis and abscess) (1,7).

TABLE 176.2
Differential Diagnosis of Angioedema

Infection
Bacterial (cellulitis, erysipelas, Ludwig angina)
Parasitic (trypanosomiasis, trichinosis, filariasis)
Pharyngitis or peritonsillar abscess
Autoimmune disorders
Systemic lupus erythematous
Sjögren syndrome
Polymyositis or dermatomyositis
Scleroderma
Tumors of the head and neck
Superior vena cava obstruction
Trauma
Burns
Congestive heart failure
Acute abdominal pathology
Urticaria
Contact dermatitis
Nephrotic syndrome
Hypothyroidism

ED EVALUATION

The diagnosis of angioedema in the acute setting is established primarily on clinical grounds. Laboratory studies are of limited utility in the ED. Nevertheless at follow-up, a number of diagnostic tests are available, including complement component C4, which is usually low in patients with HAE and AAE, but normal in allergy- and ACEI-induced angioedema, as well as C3, C1q, and C1 inhibitors, which may serve to further differentiate between HAE and AAE and their respective subtypes (1,2,4). Diagnostic imaging

similarly has little to offer in the ED. Nevertheless, for abdominal manifestations of angioedema, ultrasound and computed tomography (CT) scans of the abdomen and pelvis may be helpful to either exclude potentially dangerous alternative diagnoses or support the diagnosis of abdominal angioedema by demonstrating characteristic findings of bowel wall edema and sometimes ascites (2).

As always, initial ED evaluation of suspected angioedema should focus on airway, breathing, and circulation. As deterioration can be rapid, timely evaluation and frequent reassessment of the airway are the first priorities for the emergency physician (9). Symptoms of dyspnea, stridor, hoarseness, and voice change suggest airway compromise and have been shown in retrospective chart reviews to correlate with immediate or eventual airway intervention and ICU care (9,11). The anatomic location of the angioedema also has important prognostic implications, although the literature is limited. Retrospective chart reviews have shown that isolated edema of the face, lips, or soft palate conferred a good prognosis with no patient requiring airway intervention or ICU admission. Evidence of laryngeal edema, on the other hand, universally resulted in either airway intervention or ICU admission, while tongue edema showed no clear tendencies (2,3,11). One chart review addressed the particular use of fiber optic nasopharyngoscopy and showed that the presence or absence of laryngeal edema on fiber optic examination was highly predictive of which patients would or would not require immediate or eventual airway intervention (11). Based on these data, the authors recommend the use of fiber optic nasopharyngoscopy if available whenever there is a clinical suspicion of laryngeal edema, especially if dyspnea, stridor, hoarseness, or voice change is present or if there is significant tongue swelling.

Next, adequate circulation should be ascertained in case of suspected allergic reaction or anaphylaxis with careful blood pressure monitoring. With the airway, breathing, and circulation assessment complete and therapy initiated if needed, a goal-directed history and physical examination should follow, focusing on finding

the etiology of the angioedema, which can in turn guide the eventual medical management.

ED MANAGEMENT

The basic concepts of managing angioedema in the ED are outlined in Figure 176.1. For unstable patients who require immediate definitive airway intervention, orotracheal intubation by direct or video laryngoscopy is recommended. Concomitant preparation for cricothyrotomy is essential should direct laryngoscopy fail. If airway intervention is occurring on a less emergent basis, the safest option is nasotracheal fiber optic intubation, preferably in a controlled environment such as an operating room (2,9). Nasotracheal fiber optic intubation can be especially helpful if there is significant tongue swelling (2). Ultimately, the best choice of intubation technique will incorporate consideration of patient stability, anticipated difficulty of the airway, the provider level of comfort with the array of techniques, and local practice patterns. The risk of increasing laryngeal edema through the trauma of repeated intubation attempts should also be taken into consideration (2). Rescue airway devices such as laryngeal mask airway (LMA) and blind insertion airway devices are not effective for laryngeal edema, but may be considered if the edema is limited to the more proximal airway such as tongue and soft palate (2). Finally, any hypotension due to anaphylaxis should be treated with intramuscular or intravenous epinephrine and intravenous fluids (Fig. 176.1) (2).

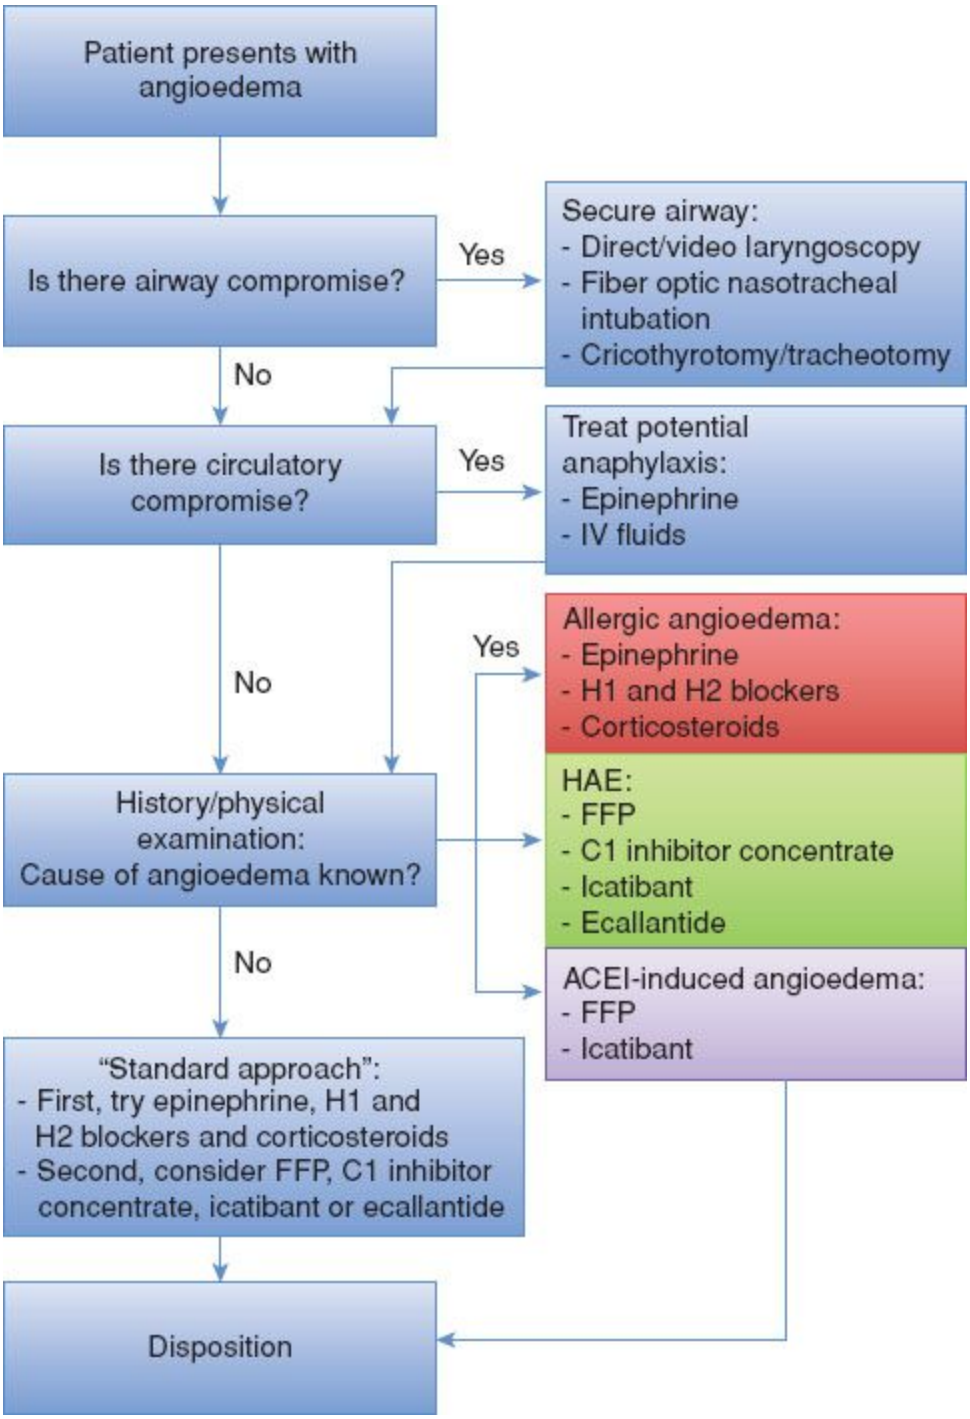

FIGURE 176.1 Clinical approach to angioedema. AAE, acquired angioedema; IV, intravenous; HAE, hereditary angioedema; FFP, fresh frozen plasma; ACEI, angiotensin-converting enzyme inhibitor. (Modified from Wilkerson RG. Angioedema in the emergency department: An evidence-based review. *Emerg Med Pract.* 2012;14(11):1–21.)

Once any airway or circulatory compromise has been addressed, a number of pharmacologic options are available to treat angioedema. It is important for emergency physicians to identify the key features of the various etiologies of angioedema because the best choice in medications depends on the underlying disease mechanism (Fig. 176.1; Table 176.1) (2). If the underlying mechanism is already known, for example, if the patient has a past medical history of HAE or presents after exposure to an obvious allergic trigger, every effort should be made to tailor therapy to these etiologies. Realistically, however, the cause of angioedema is difficult to ascertain in the ED based on history alone or using current diagnostic tools. In these cases of angioedema of unclear etiology, the authors propose a "standard approach."

In this "standard approach", all angioedema is assumed to be allergic in nature at first and treated initially with epinephrine, H_1- and H_2 blockers, and corticosteroids, since these agents are widely available, inexpensive, and generally safe (Fig. 176.1; Tables 176.1 and 176.3) (2). Epinephrine should be administered intramuscularly or in severe cases intravenously. H_1 blockers, (primarily diphenhydramine, but second-generation antihistamines can also be considered), H_2 blockers (such as cimetidine and ranitidine), and corticosteroids can be administered intravenously or orally (Table 176.3) (2). H_1 blockers offer the main antihistamine effect, though the addition of H_2 blockers may potentiate the effect as extrapolated from studies on urticaria (2). A short oral course of corticosteroids may be administered as a prophylactic measure against a rebound reaction (2). While these agents are effective for histamine-mediated allergic angioedema, they are ineffective for bradykinin-mediated ACEI-associated angioedema, HAE, and AAE (2).

TABLE 176.3
Medical Treatment of Adult Angioedema

Medication	Dose	Frequency	Route
Epinephrine 1:1,000	0.2–0.5 mg	q5–15min	IM
	0.1 mg, or 1–4 µg/min	Infusion over 5 min, or drip	IV
H_1 blocker			
Diphenhydramine	25–50 mg	q4–6h	IV/PO
H_2 blocker			
Cimetidine	300 mg	q6h	PO
Ranitidine	50 mg	q6–8h	IV
	150 mg	BID	PO
Corticosteroids			
Methylprednisolone	60–125 mg	Daily	IV
Prednisone	20–60 mg	Daily	PO
Fresh frozen plasma (FFP)	2 units/kg	×1	IV
C1 inhibitor concentrate (Berinert)	20 U/kg IV	×1	IV
Icatibant	30 mg	×1	SC
Ecallantide	10 mg	×3	SC

For angioedema of unclear etiology refractory to these first-line therapies, as well as for known HAE, and to lesser extent, ACEI-induced angioedema or AAE, there are several alternative agents for consideration. These agents include fresh frozen plasma (FFP) and several newly developed therapies: purified C1 inhibitor concentrate, icatibant, and ecallantide (Fig. 176.1; Table 176.1) (2,4). The recommended dosing for these agents is listed in Table 176.3 (2). The first of these therapies, FFP, contains exogenous C1 inhibitor and angiotensin-converting enzyme and has been shown to be effective for HAE and ACEI-induced angioedema in case reports, though not for AAE (2,12). Purified C1 inhibitor concentrate has also been shown in several clinical trials to be both effective and safe for HAE with only mild reactions reported (2,13,14). One formulation, Berinert, was recently approved in the United States for acute presentation of HAE (2). Data are currently unavailable for the effectiveness of C1 inhibitor for ACEI-induced angioedema and AAE. Icatibant and ecallantide are both agents that modify the kinin–kallikrein pathway, icatibant as a bradykinin receptor

inhibitor, and ecallantide as a kallikrein inhibitor (2,4). Like C1 inhibitor concentrate, both agents have been shown in clinical trials to be effective for acute attacks of HAE and recently approved for use in the United States (2,15,16). Both medications have a favorable side effect profile; however, rare hypersensitivity reactions including anaphylaxis have been reported with ecallantide (2,15,16,17). With the exception of case reports suggesting the effectiveness of icatibant for ACEI-induced angioedema, there is little evidence that either icatibant or ecallantide is effective for ACEI-induced angioedema or AAE (2). In summary, while purified C1 inhibitor concentrate, icatibant, and ecallantide offer great potential for the management of HAE, data on their effectiveness for ACEI-induced angioedema and AAE are limited. Moreover, these newer agents are still not available at all hospitals and can be costly, ranging from $4,700 to $9,500 per dose (2). Thus, it is suggested that these therapies be considered as second-line therapy options for angioedema of unclear etiology.

For pediatric patients presenting with acute angioedema, management is similar to that of adults, with initial emphasis on airway, breathing, and circulation (14). Epinephrine, H_1- and H_2 blockers, and corticosteroids are particularly important first-line pharmacologic interventions in pediatric patients since allergic angioedema is more common (Table 176.4) (1). For pediatric cases of HAE, FFP, and Berinert C1 inhibitor concentrate are considered appropriate therapies (Table 176.4) (14). Icatibant and ecallantide are currently not approved for pediatric use (2).

TABLE 176.4
Medical Treatment of Pediatric Angioedema

Medication	Dose	Frequency	Route
Epinephrine 1:1,000 dilution	0.01 mg/kg (max 0.3 mg)	q10–15min	IM
H_1 blocker			
Diphenhydramine	1 mg/kg (max 50 mg)	q4–6h	IV/IM/PO
H_2 blocker			
Cimetidine	Infants 10–20 mg/kg/d	Divided q12h	IV/IM/PO
	Children 20–40 mg/kg/d	Divided q6h	IV/IM/PO
Ranitidine	2–4 mg/kg/d (max 200 mg)	Divided q6–8h	IV/IM
	4–8 mg/kg/d (max 300 mg)	Divided q12h	PO
Corticosteroids			
Dexamethasone	0.6 mg/kg	Daily	IV/IM/PO
Prednisone	2 mg/kg	Daily	PO
Fresh frozen plasma (FFP)	2 units/kg	×1	IV
C1 inhibitor concentrate (Berinert)	10–20 U/kg IV	×1	IV

An often overlooked component of addressing angioedema in the ED is prevention and patient education. Patients with allergic angioedema should avoid any potential triggers including discontinuing any inciting drugs. If allergic angioedema or anaphylaxis is suspected, an epinephrine autoinjector device should be prescribed (1,2). Patients who had angioedema from one kind of ACEI should avoid other drugs within the ACEI class (2,6). Whether angiotensin receptor blockers (ARBs) should be used by patients with previous ACEI-induced angioedema is controversial, and data are limited (2). The incidence of developing angioedema in this group is estimated to be 10% or less (18,19). Nevertheless, the risk of angioedema should be weighed against the indications for ARBs, particularly in cases when ARBs are thought to be more beneficial than other antihypertensive drugs.

CRITICAL INTERVENTIONS

- Perform rapid assessment and management of airway compromise and anaphylaxis.
- Treat all cases of angioedema with epinephrine, H_1- and H_2 blockers, and corticosteroids, before considering FFP, C1 inhibitor concentrate, icatibant, or ecallantide.

- Identify potential precipitating agents, especially allergic triggers and ACEIs.

DISPOSITION

The disposition of patients with angioedema is determined by the severity of initial symptoms, the anatomic location of the angioedema, the disease course, and response to therapy. As general guideline, patients who may warrant ICU admission include those with:

- Airway compromise and laryngeal edema requiring definitive airway
- Symptoms of dyspnea, stridor, hoarseness, or voice change
- Diffuse tongue involvement

In contrast, patients who may be admitted to a floor unit or discharged home include those with:

- Involvement limited to the face, lips, and soft palate
- Localized tongue involvement (9)

The patients who are candidates for discharge should be observed for a period of at least 4 to 6 hours in the ED to ensure no further extension of the edema (2). Outpatient referral for further work-up may be appropriate, especially in cases of recurrent angioedema. Allergy skin testing for allergic angioedema, prophylactic drug regimens for HAE, and work-up for underlying malignancy or autoimmune disease for AEE may all be addressed outpatient (1,2).

Common Pitfalls

- Failure to adequately assess and manage the airway
- Failure to adequately reassess for airway deterioration
- Failure to observe low-risk patients for an adequate period of time before discharge
- Failure to address underlying precipitants and discontinue their use

CHAPTER 177

Drug Allergy and Other Drug Reactions

Paul Jhun

An adverse drug reaction (ADR) is defined by the World Health Organization as a "noxious, unintended, and undesired effect of a drug that occurs at doses used for prevention, diagnosis, or treatment" (1). ADRs occur in 10% to 20% of hospitalized patients and account for 3% to 6% of all hospital admissions (2,3), many of whom present to the emergency department for diagnosis and care.

ADRs are classified as type A or type B reactions. Type A ADRs are predictable reactions that can affect any healthy patient, given sufficient dose and duration, due to the known pharmacologic properties of the drug (drug interactions, overdose/toxicity, side effects). Type B ADRs are unpredictable hypersensitivity reactions that affect a susceptible subset of the population due to unpredictable individual immunologic response. Type B ADRs include true immunologic drug reactions, idiosyncratic drug reactions, and drug intolerance (expected side effects at subtherapeutic doses). Type A reactions constitute 80% to 90% of ADRs, while Type B reactions make up 10% to 20% of ADRs (2,3).

DRUG ALLERGY THEORY

Drug allergy or hypersensitivity accounts for 6% to 10% of ADRs. The multivalency theory proposed by Karl Landsteiner forms the current understanding of the immunologic pathophysiology of drug allergies (4). By definition, a monovalent antigen has only one site

of attachment. Landsteiner proposed that drug antigens must be presented to the immune system in multivalent form in order to: (1) sensitize the immune system, inducing immunoglobulin synthesis; and (2) activate the immune system, eliciting the mast cell and basophil release of vasoactive mediators. Multivalency can be achieved through four main mechanisms: (1) the antigen is already a large macromolecule with multiple repeating epitopes, such as recombinant proteins, antisera, vaccines, or insulin; (2) the antigen is a hapten, a small molecule able to bind with larger macromolecules, that can form a multivalent hapten-carrier complex, such as β-lactam antibiotics, heavy metals, antithyroid medications, or quinidine; (3) the antigen undergoes metabolism, generating intermediate haptens capable of forming multivalent hapten-carrier complexes, such as antimicrobial sulfonamides, phenytoin, procainamide, or acetaminophen; or (4) the antigen directly binds certain T-cell receptors and activates the immune system, such as sulfamethoxazole, carbamazepine, lamotrigine, or lidocaine (5). Of note, a few small molecules have multiple recurrences of a single epitope, creating an inherently multivalent antigen, such as succinylcholine.

Risk factors predisposing a patient to drug hypersensitivity reactions include the genetic predisposition of the patient (history of atopy, history of prior drug reactions, and familial propensity), the characteristics of the drug (inherent reactivity, preparation, dosage, frequency, and duration of therapy), and the disease state (concomitant medications or diseases). Interestingly, specific drug hypersensitivity reactions have been associated with certain disease states, such as when sulfonamides are administered to patients with AIDS or when amoxicillin is administered to patients actively infected with Epstein–Barr virus (6,7).

CLINICAL PRESENTATION

Classification of Reactions

Drug hypersensitivity reactions are conceptually categorized according to the Gell and Coombs four-group classification system:

type I acute IgE-mediated response, type II delayed IgG/IgM-mediated cell destruction, type III delayed immune complex reaction, and type IV delayed T-cell-mediated hypersensitivity.

Type I reactions are mediated by previously sensitized patients who have preformed drug-specific IgE antibodies attached to the surface of their mast cells and basophils. When the patient is re-exposed to the offending drug, the circulating drug antigen binds the drug-specific IgE antibodies activating the mast cells and basophils, leading to immediate vasoactive mediator release and clinical sequelae such as urticaria, flushing, pruritis, angioedema, laryngeal edema, bronchospasm, gastrointestinal distress, and hypotension.

Type II cytotoxic reactions result when an offending drug binds to certain cell types and acts as an antigen. When drug-specific IgG or IgM antibodies bind these complexes, the cells are destroyed. Almost all type II reactions involve formed elements of the blood leading to hemolytic anemia, thrombocytopenia, or neutropenia, and their respective clinical sequelae.

In type III reactions, the drug antigen binds drug-specific IgG, forming immune complexes that precipitate in various tissues, clinically presenting as serum sickness, drug fever, or vasculitis.

Type IV reactions are mediated by sensitized T lymphocytes that recognize a particular drug antigen and recruit other lymphocytes and mononuclear cells to the site of that antigen. Type IV reactions classically have prominent dermatologic findings due to the fact that there are nearly twice as many T cells residing in the skin compared to circulation (8). Clinical manifestations include contact dermatitis, morbilliform or maculopapular eruptions, exfoliative dermatitides, or drug-induced hypersensitivity syndrome. However, type IV reactions may also involve specific organs without cutaneous findings, such as isolated drug-induced hepatitis, interstitial nephritis, or pneumonitis.

The World Allergy Organization proposed a simpler, two-group clinical classification system to help practitioners identify IgE-mediated reactions, based on the timing of symptom onset: immediate and delayed reactions (9). Immediate reactions are those

beginning within 1 hour of first dose administration and are likely IgE-mediated type I reactions. Delayed reactions are those appearing after 1 hour of dose administration and are not likely to be IgE-mediated.

Drug reactions that resemble type I IgE-mediated hypersensitivity reactions, but are not immune-mediated, are termed *idiosyncratic* or *pseudoallergic* reactions. Most pseudoallergic reactions are clinically indistinguishable from true allergic reactions because they often share the final common pathway of mast cell and basophil activation. Of note, the term *anaphylaxis* is reserved for immune-mediated type I hypersensitivity reactions, while the terms *anaphylactoid* and *nonallergic anaphylaxis* are preferred for idiosyncratic reactions. Common medications and their idiosyncratic reactions include radiocontrast media (RCM)-induced urticaria and hypotension, opiate-induced urticaria, aspirin-induced bronchospasm, nonsteroidal anti-inflammatory drug-induced urticaria, and vancomycin "red man syndrome."

DIFFERENTIAL DIAGNOSIS

Given the broad spectrum of clinical presentations of drug adverse reactions, physicians should include ADRs as part of their differential diagnosis.

ED EVALUATION

The diagnosis of drug hypersensitivity reactions in the emergency department is largely dependent on the patient history and presentation. Particularly for the emergency physician, early recognition and diagnosis of anaphylaxis is critical, while recognition of severe exfoliative dermatitides and drug-induced hematopoietic or organ damage is important in determining appropriate management and disposition. Important historical information includes assessing risk factors such as previous exposures to the same or similar drugs, a complete list of medications to determine allergenic potentials, and temporal association of drug administration times to symptom onset to

establish a causal link. Improvement of symptoms after withdrawal of the suspected drug is suggestive information. A suspicion for immune-mediated cell destruction should prompt the physician to obtain a complete blood count with a peripheral smear. An indirect Coombs test, if available, may be helpful in diagnosing immune hemolytic anemia.

While objective testing is available for certain drug allergic reactions, such tests require referral to an allergy–immunology specialist for implementation and interpretation. Skin testing is conducted primarily to evaluate suspected type I hypersensitivity reactions, although limitations include lack of standardization and validation for many drugs. Patch testing can be performed for evaluating contact dermatitis caused by topically applied medications. In vitro tests, such as radioallergosorbent or enzyme-linked immunosorbent assay tests are largely investigational and not standardized or validated, so are of limited value. Drug provocation testing by graded challenges can be performed, but should be done so by appropriate specialists after careful consideration of risks and benefits for a particular individual. The best studied drug allergen testing involves penicillin. Intradermal skin testing is the diagnostic procedure of choice for evaluating suspected IgE-dependent penicillin allergy (5,7).

ED MANAGEMENT

The standard management of drug hypersensitivity reactions includes prompt discontinuation of the medication and provision of supportive care that is specific to the type and severity of manifestations. Mild pruritis, flushing, and urticaria may be treated with antihistamines. Corticosteroids may be indicated for severe systemic or cutaneous reactions, immune complex reactions, or drug-induced hematologic diseases. Early epinephrine is the mainstay of treatment for anaphylactic reactions. Oxygen and airway support, inhaled β-agonists, intravenous fluids, and pressors also may be required.

Although type B ADRs are unpredictable, several steps can be taken to minimize the chance of developing a drug hypersensitivity reaction. Perhaps most importantly, medications should be prescribed only when necessary. A careful history of risk factors for drug reactions, including prior ADRs, should be obtained. If a drug allergy exists, crossreactive drugs should be avoided. The oral route should be used when possible (1,5,7). Preparations that are less sensitizing are preferred when available. Documentation in the medical record of any apparent reaction may help avert a similar or worse reaction in the future. Finally, when potentially immunogenic parenteral agents are given in the emergency department, patients should be observed for at least 1 hour after administration, to ensure an immediate IgE reaction does not occur.

CRITICAL INTERVENTIONS

- Recognize and administer epinephrine promptly for anaphylaxis (adult: epinephrine 0.2 to 0.5 mg [1:1,000 {1 mg/mL} solution] IM, or epinephrine 0.1 mg [1:10,000 {0.1 mg/mL} solution] IV; pediatric: epinephrine 0.01 mg/kg [1:1,000 {1 mg/mL} solution] IM, maximum single dose of 0.3 mg) (10)
- Obtain, document, and be aware of a history of prior drug hypersensitivity reactions
- Identify and withdraw offending drug(s) and provide alternative drug therapy if indicated

DISPOSITION

Disposition decisions for patients with drug reactions hinge on the nature and severity of the reaction. Patients who present with mild reactions, respond well to treatment, and are reliable with good support systems may be considered for expedited discharge to home. In borderline cases, a period of observation of several hours may be helpful. Patients with persistent or recurring airway edema, bronchospasm, hypotension, cardiovascular complications, or altered mental status require admission to the hospital in an intensive care setting. Patients who receive treatment for an initially

severe reaction but who rapidly improve are typically either observed for a period of 6 to 12 hours or admitted to the hospital; in the case of anaphylaxis, this facilitates treatment if a late-phase reaction occurs. Discharged patients should receive instructions including cautions regarding possible delayed or recurrent reactions. Referral to or consultation with an allergy–immunology specialist is indicated in suspected cases of drug hypersensitivity reactions, especially suspected cases of IgE-mediated reactions. Further testing can be performed and patients can be evaluated for induction of drug tolerance or desensitization for offending drugs that are medically necessary.

PENICILLIN ALLERGY AND CROSSREACTIVITY

Penicillin and its derivatives are among the most widely prescribed antibiotics and are the most common cause of drug-induced allergic reactions. Penicillin can be responsible for any of the four types of Gell and Coombs. The overall incidence of reported adverse reactions to penicillins is estimated to be up to 10% of patients (7). Interestingly, up to 90% of these individuals are able to tolerate penicillin after complete evaluation and testing (7). This could be due to inaccurate clinical history of penicillin allergy or more importantly could be due to the gradual loss of penicillin-specific IgE that happens in patients over time. Studies have shown that approximately 50% of patients with IgE-mediated penicillin allergy lose sensitivity 5 years after their last reaction, and approximately 80% lose sensitivity after 10 years (11,12). Life-threatening anaphylaxis secondary to penicillin after parenteral administration appears to be uncommon, with an incidence of 1 to 2 per 10,000 treated patients (7). Patients with a suspected history of IgE-mediated penicillin allergic reaction should be referred to an allergy–immunology specialist to undergo skin testing, which is the most reliable method for evaluating IgE-mediated penicillin allergy. In patients who report a reaction history concerning for anaphylaxis, especially if the reaction was recent, penicillins and

crossreactive drugs should generally be avoided until evaluation by a specialist.

Regarding crossreactivity risks with the use of the other β-lactam antibiotics in a patient with a confirmed penicillin allergy, crossreactivity rate is high with first-generation cephalosporins and these drugs should generally be avoided. Most second- and all third- and fourth-generation cephalosporins appear to have negligible crossreactivity (13). Carbapenems appear to have low crossreactivity rates of about 1% in limited studies (14,15). Monobactams do not appear to immunologically crossreact, likely due to its distinctly different chemical structure (5,7). Overall, recent studies have shown that cephalosporin administration in patients with a reported history of penicillin allergy, unconfirmed by skin testing, resulted in an allergic reaction in 1% of patients, while cephalosporin administration in patients with confirmed penicillin-allergy patients resulted in an allergic reaction in 2% of patients (7,13). A recent consensus allergy and immunology guideline states that patients with a complete, negative penicillin skin testing may receive cephalosporins safely (7). However, if the patient has a reported history of penicillin but has not received skin testing, this guideline states that the practitioner has the option of either (1) obtaining penicillin or cephalosporin skin testing to determine the safety of cephalosporin administration or (2) directly administering the cephalosporin (only in the absence of severe and/or recent penicillin allergy reaction history), with the knowledge that there is a very small but real risk for allergic reaction. In such cases of direct cephalosporin administration in a patient with a reported but unconfirmed history of penicillin allergy, crossreactivity risk can be further mitigated by administering a third- or fourth-generation cephalosporin.

RADIOCONTRAST MEDIA REACTIONS

More than 15 million diagnostic radiographic examinations using RCM are performed in the United States each year. Adverse reactions due to RCM are reported to have an annual incidence of

2% to 12%, with deaths estimated between 1 to 3 per 100,000 administrations (16,17). RCM adverse reactions can be categorized into hypersensitivity reactions and chemotoxic reactions.

RCM-induced hypersensitivity reactions are further divided into immediate and delayed types. Immediate hypersensitivity reactions generally present within 1 hour of administration and are believed to be idiosyncratic, nonimmune-mediated, and independent of dose and infusion rate. These acute reactions share the final common pathway of mast cell activation and vasoactive mediator release, are clinically indistinguishable from type I reactions, and are treated similarly. Delayed RCM hypersensitivity reactions are type IV reactions that can present several days after administration and are generally self-limited (18).

As newer generation RCM products have been developed, the incidence of adverse reactions has also decreased. First-generation RCMs are ionic monomers that are categorized as high-osmolar RCM (>1,400 mOsm/kg), compared with normal serum osmolality. Second-generation agents, such as iohexol, are nonionic monomers that are categorized as low-osmolar RCM (500 to 900 mOsm/kg). The newest agents are nonionic dimers, such as iodixanol, that have the same osmolality of plasma and are categorized as iso-osmolar RCM. Estimated rates of severe, immediate hypersensitivity reactions are 0.1% to 0.3% for the high-osmolar RCM and 0.01% to 0.04% for low-osmolar RCM (1,17). Of note, seafood or shellfish allergy is not an independent risk factor for RCM hypersensitivity reactions and no special precautions need to be taken for such patients (1).

Chemotoxic RCM reactions are related to the RCM chemical properties and are dependent on dose and infusion rate. These reactions include nephrotoxicity, vasovagal reactions, and iodine-induced thyroid dysfunction. Regarding contrast-induced nephropathy (CIN), there is no specific treatment once acute kidney injury develops, so management is aimed at prevention. The mechanism of CIN is thought to be related to renal vasoconstriction and/or direct renal cytotoxic effects of the contrast agent, and the diagnosis is based on the increase in the serum creatinine level

beginning within 24 to 48 hours of RCM administration. Risk factors for CIN include chronic kidney disease, diabetes mellitus, multiple myeloma, and causes of reduced renal perfusion such as advanced heart failure and hypovolemia. A high total dose of RCM as well as first-generation RCM are additional risk factors. The use of low osmolar or iso-osmolar RCM in patients with pre-existing chronic kidney disease is associated with decreased incidence of CIN compared to high osmolar RCM (19,20).

The risk-to-benefit ratio of a contrast study should be considered before it is ordered and performed. If possible, ultrasound or magnetic resonance imaging should be utilized. If RCM must be used and the patient has a history of prior anaphylactoid reaction, the patient can be pretreated with corticosteroids and antihistamines to decrease the likelihood of recurrent anaphylactoid reaction. One common protocol is shown in Table 177.1. To minimize the risk of developing CIN, recommended approaches have included infusion of isotonic sodium chloride or sodium bicarbonate before and after the administration of contrast (e.g., 3 mL/kg/hr for 1 hour before and 1 mL/kg/hr for 6 hours after) (20). Also, while evidence is conflicting, some suggest benefit from adjunctive treatment with N-acetylcysteine, 1,200 mg bid the day before, and the day of the radiocontrast administration (20). Finally, nonsteroidal anti-inflammatory drugs should be avoided as they increase the risk of nephrotoxicity.

TABLE 177.1
Premedication Protocol Prior to Administration of Radiocontrast Media to a Patient with Prior History of Anaphylactoid Reaction

Time Prior to Contrast Administration (hr)	Medication
13	Prednisone 1 mg/kg PO
7	Prednisone 1 mg/kg PO
1	Prednisone 1 mg/kg PO and diphenhydramine 1 mg/kg PO/IM[a]

[a]H2-antihistamine may also be included, if desired.

Common Pitfalls

- Failure to obtain medication list and drug allergy history
- Administration of crossreactive drugs to patients with a known drug hypersensitivity reaction
- Failure to diagnosis and quickly manage anaphylaxis

CHAPTER 178

Multisystem Autoimmune Disease

Theodore I. Benzer

Patients with multisystem autoimmune disorders may present for initial medical evaluation with a bewildering array of symptoms or complaints. Many of the tests needed to diagnose these “rheumatic disorders” cannot be performed during an emergency department (ED) visit. However, the emergency physician must recognize that an autoimmune disorder may be responsible for the patient’s clinical picture and must decide which patients require admission and which can safely undergo an outpatient evaluation. Likewise, when a patient with known multisystem autoimmune disease presents to the ED with new symptoms, the physician must determine whether they represent an exacerbation of known disease, a manifestation of an unrelated disorder, or a complication of therapy.

Evolving therapies and variations in individual response to treatments make rheumatologic consultation appropriate in many cases. Although the ultimate cause of the autoimmune disorders remains a mystery, it is increasingly clear that specific autoantibodies directed against cellular components are markers for, and probable causes of, many of the manifestations. Positive tests for these antibodies not only correlate with current symptoms but are also predictive of the patient’s course. The use of these specific disease markers can improve accuracy in diagnosis and can guide therapy directed at specific pathologic entities.

Despite the fact that definitive therapies for most autoimmune disorders are lacking, there is often much that can be done to

alleviate symptoms and prevent progression of tissue damage. Every pharmacologic treatment has a potential for toxicity that must be balanced against the potential benefit it may provide to the patient.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is the prototypical autoimmune disease. Its prevalence is 1 in 2,000 with a 10:1 predominance of women over men and a predilection for nonwhites. The prevalence is 1 in 750 for black women between the ages of 20 and 64 (1).

The cause of SLE remains unknown; hormonal, metabolic, genetic, environmental, and infectious factors have all been proposed as etiologic agents. The pathophysiology of SLE involves the production of autoantibodies initiated by an unknown stimulus. These antibodies react with cell constituents and initiate an inflammatory response that results in the activation of the complement pathway and the elaboration of chemotactic factors and other inflammatory mediators. Antibody-dependent cytotoxic leukocytes are also activated.

Antinuclear antibodies (ANAs) are almost invariably detected in patients with SLE. Although ANAs are found in low titers in many other autoimmune and nonrheumatologic disorders, high titers are more specific for SLE. High titers of antibodies to double-stranded DNA are seen only in patients with SLE (2). Antibodies to the Smith antigen are also specific for SLE, as well as being associated with more severe symptoms. During active SLE, complement levels are depressed and may be helpful in following the course of disease (1).

CLINICAL PRESENTATION

SLE can affect any tissue or organ and has been said to have replaced syphilis as “the great imitator” of other diseases (1). Patients often make multiple visits to physicians before SLE is initially recognized. Some of the more common manifestations are listed in Table 178.1.

TABLE 178.1
Systemic Lupus Erythematosus: Characteristic Features and Suggestive Signs and Symptoms

System	Presentation
Constitutional	Fever, fatigue, malaise, weight loss
Vascular	Raynaud phenomenon, arterial occlusion, extremity ulcers
Dermatologic	Diffuse alopecia, malar rash, discoid rash, photosensitivity
Hematologic	Hemolytic anemia, leukopenia, thrombocytopenia, thrombosis
Immunologic	False-positive serologic test for syphilis
Gastrointestinal	Nausea, vomiting, oral ulcers
Cardiac	Pericarditis, myocarditis
Pulmonary	Diffuse interstitial pneumonitis, pleuritis, pleural effusion
Musculoskeletal	Nonerosive arthritis
Renal	Glomerulonephritis, nephrotic syndrome
Reproductive	Spontaneous abortion, preeclampsia
Neurologic	Psychosis, depression, mania, seizures, headache, organic brain syndrome, aseptic meningitis, peripheral neuropathy

The most typical initial complaints are fatigue and arthralgias, but fever, anemia, anorexia, and a malar rash are other common presenting symptoms. The arthralgias are commonly fleeting and migratory, typically appearing in the proximal interphalangeal and metacarpophalangeal joints, the wrists, and the knees, but they may also be due to frank synovial inflammation.

The rash of SLE varies from a slight blush to a well-demarcated and somewhat edematous maculopapular erythematous eruption covering both cheeks and the bridge of the nose. It tends to spare the nasolabial folds but can cause scarring and atrophy of skin structures. The rash is characteristically exacerbated by sun exposure and may often cause a patient to seek medical attention before any other symptoms of SLE have developed.

Although the kidneys are commonly affected in SLE, nephrotic syndrome and peripheral edema are rarely seen before other manifestations of disease have led to the diagnosis of SLE (3). Patients with SLE frequently present with acute, potentially life-

threatening problems. Complaints of chest pain, abdominal pain, and neurologic dysfunction can indicate an acute flare of disease or a serious complication of therapy. Patients with acute chest pain, with or without fever, may have pleuritis, pericarditis, or pneumonitis. Abdominal pain may indicate an acute flare of polyserositis.

Neurologic problems of virtually any type may be seen in SLE. Most common are central disorders ranging from mood disorders to frank psychosis. Seizures are also common, especially in younger patients. SLE should be in the differential diagnosis of new-onset seizures, especially in young women.

The lupus anticoagulant, also called the anticardiolipin antibody or antiphospholipid antibody, is an antibody that produces an artifactually prolonged partial thromboplastin time in vitro but a "paradoxical" procoagulant effect in vivo. Although antiphospholipid antibodies are associated with SLE, they may occur as a part of a distinct pathologic entity referred to as the antiphospholipid syndrome (4,5). Both conditions can lead to deep venous thrombi, pulmonary emboli, stroke, chronic ulcers of the extremities, and thrombocytopenia (4,5). Patients with recurrent or unusual thrombosis should be evaluated for antiphospholipid autoantibody and SLE (6). Recent studies have shown that patients with the antiphospholipid syndrome are at increased risk for cardiovascular disease.

Patients with known SLE may present to the ED with either exacerbations of their disease or complications of therapy.

DIFFERENTIAL DIAGNOSIS AND ED EVALUATION

Given the variety of possible presentations, the differential diagnosis of SLE is exceedingly broad. A thorough history and physical examination are required to identify multisystem involvement and recurrent symptoms. The differentiation of SLE from the other autoimmune syndromes may require repeated rheumatologic evaluation and specific autoantibody testing.

Tan et al. (7) have published a list of 11 criteria diagnostic for SLE (Table 178.2). The diagnosis is established if 4 or more of these findings are present serially or simultaneously. A medication history must be elicited to rule out drug-induced lupus. Attention to detail in evaluating the patient with nonspecific symptoms may lead one to suspect the diagnosis of SLE. The diagnosis should be particularly entertained in women of childbearing age who have recurrent or vague symptoms that do not clearly point to a discrete disease entity.

TABLE 178.2
Diagnostic Criteria for Systemic Lupus Erythematosus[a]

1. Malar rash	Fixed erythema, flat or raised, over the malar eminences.
2. Discoid rash	Erythematous raised patches with adherent keratotic plugging. Atrophic scarring may occur.
3. Photosensitivity	
4. Oral ulcers	Incudes oral and nasopharyngeal, observed by physician.
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion.
6. Serositis	Pleuritis or pericarditis documented by electrocardiogram or rub or evidence of pericardial effusion.
7. Renal disorder	Proteinuria >0.5 g/d, or >3+, or cellular casts.
8. Neurologic disorder	Seizures without other cause or psychosis without other cause.
9. Hematologic disorder	Hemolytic anemia or leukopenia (<4,000/μL), or lymphopenia (<1,500/μL), or thrombocytopenia (<100,000/μL) in the absence of offending drugs.
10. Immunologic disorder	Positive lupus erythematosus cell preparation or anti-dsDNA or anti-Sm antibodies or false-positive VDRL.
11. Antinuclear antibodies	An abnormal titer of ANAs by immunofluorescence or an equivalent assay at any point in time in the absence of drugs known to induce ANAs.

ANAs, antinuclear antibodies.
[a]If four of these criteria are present at any time during the course of disease, a diagnosis of SLE can be made with 98% specificity and 97% sensitivity.

Drug-induced SLE is a distinct entity that has been associated with many medications, including procainamide, hydralazine, anticonvulsants, chlorpromazine, isoniazid, methyldopa, penicillamine, quinidine, propylthiouracil, and sulfasalazine. Drug-induced SLE has a milder course than idiopathic SLE and does not cause renal or central nervous system involvement (8). Specialized ANA testing panels reveal only histone-binding ANAs rather than the multiple varieties characteristic of SLE (1).

The evaluation of patients with established SLE should focus on the presenting complaint. However, attention should also be given to signs and symptoms of the potentially life-threatening

complications of SLE, such as thrombotic disease, pleural and pericardial effusions, and infections secondary to immunosuppressive therapy.

Patients presenting with new-onset monoarthritis or oligoarthritis generally require diagnostic arthrocentesis to rule out infection or crystal-induced arthritis. Fluid should be sent for Gram stain, culture, cell count and differential, and examination for crystals. The synovial fluid in autoimmune arthritis is typically inflammatory, with an elevated white cell count (20,000 to 80,000/μ L mixed polymorphonuclear cells and lymphocytes), a negative Gram stain, and no crystals.

The specific organs affected by SLE and the severity of the disease vary widely between individuals and over time in any given individual. Not only does the variability of the disease make diagnosis difficult, but, with the exception of the characteristic rash, each of the manifestations of lupus may occur from other causes. Although a presentation of one of these conditions alone would not prompt consideration for autoimmune disease, recurrent symptoms or the sequential development of multiple conditions associated with lupus warrants referral for ANA testing.

ED MANAGEMENT

The specific presentation dictates the management indicated in the ED. Patients presenting with mild symptoms may require nothing more than screening for renal and hematologic involvement with a urinalysis and complete blood cell count. More severe symptoms are managed as in any other disease. For example, a large pleural effusion should be tapped, and anticoagulation should be started for thromboembolic disease.

ST elevations and PR depressions seen on the electrocardiogram that are associated with a pericardial friction rub indicate pericarditis. If pericarditis is suspected, a careful evaluation should be made for signs of pericardial tamponade including a bedside echocardiogram if available. Elevated neck veins, elevated pulsus paradoxus, or hypotension should prompt a formal urgent

echocardiogram to rule out tamponade. Infectious complications should be considered in patients with established disease who are taking chronic immunosuppressive medications.

Patients with significant pleural or pericardial effusion, or any thrombotic complication, require hospital admission and rheumatologic consultation. Immunosuppressed patients with documented infection require admission for parenteral antibiotics.

Neuropsychiatric complications are frequent in SLE. Cerebritis, aseptic meningitis, seizures, ischemic strokes, peripheral neuropathy, and acute psychosis are all recognized manifestations of SLE. Corticosteroid treatment and other immunosuppressive agents predispose to infectious meningitis and corticosteroid-induced psychosis.

The acute presentation of an SLE patient with a neuropsychiatric complaint is always a challenge. The diagnosis of lupus flare should be made only after infectious etiologies have been ruled out. Patients presenting with severe disease are often treated with "stress" doses of corticosteroids (hydrocortisone, 100 mg intravenously, or methylprednisolone, 125 mg intravenously) and often receive empiric broad-spectrum antibiotic coverage after samples of blood, urine, sputum, and possibly cerebral spinal fluid are obtained for culture.

Patients with established disease who present with a flare of symptoms may require the initiation of corticosteroids or an increase in the dose. When more than 5 to 10 mg of prednisone a day is required, many rheumatologists prescribe combination therapy in an effort to limit adverse effects. Medications commonly used include nonsteroidal anti-inflammatory drugs (NSAIDs), antimalarial agents, cyclophosphamide, and mycophenolate mofetil. More recently B-cell inhibitors, including rituximab and belimumab, have been found useful in treatment of SLE patients resistant to more traditional therapy. Because every therapeutic agent has adverse effects, the risks of medication must be weighed against the morbidity of the clinical presentation. The aggressiveness and urgency of treatment depend on the presence of major organ

involvement. Changes in a patient's usual medication regimen are best carried out in conjunction with the patient's rheumatologist.

DISPOSITION

Patients with suspected or newly diagnosed SLE may be managed as outpatients, if the manifestations are mild and a life-threatening pathologic process is absent. An ANA panel should be ordered. Rheumatologic consultation can be obtained by telephone concerning any further studies, initiation of corticosteroid therapy, and appropriate follow-up. Newly diagnosed patients with SLE should be educated about the importance of adequate sleep and avoidance of ultraviolet light. Ibuprofen and estrogens may exacerbate disease and should be avoided (3). Hypertension should be controlled vigorously because it appears to have a synergistic effect in exacerbating renal disease. In drug-induced lupus, after the medication is discontinued, symptoms usually resolve within days to weeks (8,9).

Common Pitfalls

- Failure to recognize vague, atypical complaints as a presentation of SLE or other autoimmune disease.
- Failure to include SLE in the differential diagnosis of patients with pericarditis, pleuritis, renal dysfunction, neurologic symptoms, or recurrent venous thrombosis.
- Failure to differentiate disease exacerbation from an adverse effect of therapy.
- Failure to suspect infection in an immunosuppressed patient.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic autoimmune disorder characterized by widespread synovial inflammation and, often, progressive destruction of joints. It affects women three times as often as men. The prevalence increases with age and is approximately 1%.

The pathophysiology of RA involves the production of immunoglobulins against native IgG; these immunoglobulins are referred to as rheumatoid factor. Helper T-cells are also activated and produce lymphokines that promote cellular proliferation (10). Recently, researchers have identified autoantibodies to the citrullinated protein filaggrin that seem to be sensitive and specific for RA. Citrullinated proteins are exclusively produced in the synovial tissue. These autoantibodies to citrullinated proteins may be the initial target of the autoimmune response in RA (11). Activation of the inflammatory response leads to the elaboration of vasoactive substances, chemotactic factors, and complement in synovial tissues. Mononuclear cells infiltrate the subsynovial stroma, and polymorphonuclear cells appear in the synovial fluid. A "pannus" of inflamed, thickened, redundant synovium invades and replaces cartilage and periarticular bone and tendon. Polymorphonuclear cells in the synovial fluid release lysozymes that break down hyaluronic acid polymers in the synovial fluid and articular cartilage (1). Although the symptoms and signs are primarily related to the joints, RA is a multisystem autoimmune disease that frequently involves the heart, lungs, and blood.

CLINICAL PRESENTATION

RA typically presents initially as constitutional symptoms such as low-grade fever, weight loss, fatigue, and lymphadenopathy. Joint stiffness in the morning or after periods of inactivity may also be a complaint.

Articular symptoms initially involve any number or size of joints. Either arthralgia (pain) or arthritis (inflammation) may be present in an unpredictable pattern. Later, in established disease, the typical symmetric pattern of arthritis develops.

The most commonly affected joints are the metacarpophalangeal and proximal interphalangeal joints, wrists, knees, and upper spine. Although some cases of RA remain mild or even resolve, the typical course is one of unpredictable exacerbations and remissions with progressive deformity and disability.

As tissue damage progresses, typical ulnar deviation of the carpometacarpal joints and valgus deformity of the knees develop. Baker cysts may develop in the popliteal fossa. Of prime importance for the emergency physician is the development of instability of the atlantoaxial joint, with laxity and even rupture of the transverse ligament. The result is an unstable cervical spine, which may lead to spinal cord compression following even apparently trivial injury (6).

RA is a systemic disease. Over time, subcutaneous nodules over the elbows, occiput, and sacrum, thought to be vasculitic in origin, develop in 20% to 25% of patients. Pericarditis, pleuritis, pulmonary fibrosis, scleritis, Sjögren syndrome, nerve entrapment, and vasculitis may also occur. Felty syndrome, consisting of splenomegaly, anemia, thrombocytopenia, and granulocytopenia, sometimes complicates RA.

DIFFERENTIAL DIAGNOSIS AND ED EVALUATION

RA is rarely misdiagnosed when it reaches the stage of symmetric polyarthritis in characteristic joints. At earlier stages, or with milder involvement, the clinical picture may be suggestive of inflammatory or infectious joint disease or other autoimmune diseases. When joint manifestations become apparent, infectious and crystalline synovitis must be considered.

In practice, most patients presenting to the ED with oligoarthropathy should have joint aspiration to rule out infection or crystal-induced arthritis. Although RA or another autoimmune disorder may be suspected, the definitive diagnosis is made at follow-up, when further data, such as final culture results, rheumatoid factor tests, and response to anti-inflammatory therapy, are available.

In 2010, the American College of Rheumatology and the European League against Rheumatism developed new diagnostic criteria that focus on early diagnosis (Table 178.3) (12). In practice, most such patients presenting to the ED must have other significant disease ruled out (e.g., infectious arthritis, SLE). Although there may

be a suspicion of RA, the definitive diagnosis is usually made on further evaluation at follow-up.

TABLE 178.3
ACR/EULAR Criteria for the Diagnosis of Rheumatoid Arthritis

Target population (who should be tested?): Patients who	
1. have at least one joint with definite clinical synovitis (swelling)	
2. have synovitis not better explained by another disease	
Classification criteria for RA (score-based algorithm: Add score of categories A–D; a score of >6/10 is needed for classification of a patient as having definite RA)	
A. Joint involvement	Score
1 large joint	0
2–10 large joints	1
1–3 small joints (with or without involvement of large joints)	2
4–10 small joints (with or without involvement of large joints)	3
>10 joints (at least one small joint)	5
B. Serology (at least one test result is needed for classification)	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-phase reactants (at least one test result is needed for classification)	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of symptoms	
<6 wks	0
>6 wks	1

RF, rheumatoid factor; ACPA, anticitrullinated protein antibodies; CRP, c-reactive protein; ESR, erythrocyte sedimentation rate.

From Aletaha D, Neogi T, Silman AJ, et al. Rheumatoid arthritis classification criteria: An American College of Rheumatology/European League against rheumatism collaborative initiative. *Ann Rheum Dis*. 2010;69:1580–1588.

Patients with known RA who present with an exacerbation of joint inflammation require evaluation for possible secondary infections or crystalline arthropathy. Others may present with new systemic symptoms. Although the problem may be related to RA, this relationship should not be assumed to be the case until other

serious causes have been excluded. Evaluation based on presentation should be pursued as in any patient without RA. Special consideration should be given to complications of therapy; for example, pulmonary interstitial disease may be a result of either RA or treatment.

If a diagnosis of RA is considered, a rheumatoid factor titer should be ordered. If other autoimmune disorders are considered possible, other autoantibody titers, complement levels, and an erythrocyte sedimentation rate (ESR) may be indicated. Monoarticular or oligoarticular arthritis should cause one to consider crystalline and infectious arthritis. Joint aspiration is indicated, as well as oropharyngeal and genital cultures for *Neisseria gonorrhoeae.*

Few laboratory test results are abnormal in RA, and the results tend to be nonspecific. The ESR is elevated and parallels disease activity. There may be a mild normocytic anemia. A test for mixed cryoglobulins, reflecting large amounts of circulating immune complexes, may be positive, but complement levels are usually normal. Arthrocentesis of involved joints typically yields sterile fluid with hallmarks of inflammation such as decreased mucin clot formation and 20,000 to 80,000 white blood cells per microliter, of which 50% to 70% are polymorphonuclear cells (13). The classic laboratory finding of a positive serum rheumatoid factor is found in 80% of patients, but a positive rheumatoid factor can also be found in 1% to 5% of persons without RA (e.g., patients with other rheumatic disorders, leprosy, tuberculosis, liver disease, or bacterial endocarditis).

ED MANAGEMENT AND DISPOSITION

NSAIDs are the mainstay of chronic treatment of RA. Patients experiencing a flare of known disease often require therapy in addition to NSAIDs. These therapies include heat modalities, antimalarial agents, sulfasalazine, methotrexate, and surgical replacement of joints. Recently, several biologic therapies have become available for RA that interfere with the action of tumor necrosis factor, B-cells, T-cells, and interleukin-6. These drugs have

been shown to improve symptoms and slow progression of disease in those patients who have had an inadequate response to traditional therapies (14,15).

Corticosteroids are usually reserved for the treatment of extra-articular manifestations. Each of the therapeutic agents has associated adverse effects. Sulfasalazine may cause leucopenia. The antineoplastic agents can cause myelosuppression and a host of other adverse effects. Biologic therapy has been associated with infections and may be associated with increased incidence of demyelinating disease, lymphoma, and worsening symptoms of congestive heart failure. These antineoplastic and biologic agents should be initiated only after discussion with a rheumatologist who will be observing the patient.

Appropriate disposition depends on the severity of the presenting symptoms. Outpatient treatment is appropriate in individuals who do not appear toxic, including those with a new diagnosis of RA. These patients should be started on a standard dose of an NSAID and have rheumatologic follow-up arranged. Patients who appear ill require hospital admission for more intensive evaluation to rule out infectious disorders and rheumatologic consultation. Hospitalization may be required for social reasons or when disability prevents adequate functioning at home.

Common Pitfalls

- Prescribing corticosteroids as a first-line therapy for RA.
- Failure to recognize nonspecific complaints as a manifestation of autoimmune disease.
- Failure to consider possible C1–C2 instability when intubating an RA patient.

SCLERODERMA

Scleroderma (or systemic sclerosis) is an autoimmune disorder characterized by abnormal collagen production that results in pathologic fibrosis of the skin and internal organs. It occurs equally in all races and geographic areas, but it is four times more common

in women than in men. In most cases, the onset is during the third decade of life (16). The course is typically progressive over decades, but it may be fulminant and fatal. Collagen accumulation and endothelial cell proliferation in the vascular intima lead to severe narrowing of the arterial lumen.

Scleroderma can be classified according to its predominant manifestations. The CREST syndrome consists of subcutaneous calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia and is associated with a specific antibody (17,18). “Diffuse scleroderma” denotes the full systemic disease. A third subset is mixed connective-tissue disease or undifferentiated connective-tissue disorder, which combines features of SLE, scleroderma, and polymyositis. Clinical criteria have been developed for the diagnosis of systemic sclerosis (Table 178.4).

TABLE 178.4
Clinical Criteria for the Diagnosis of Systemic Sclerosis

Major Criterion	
Proximal scleroderma	Typical sclerodermatous skin changes involving areas proximal to the metacarpophalangeal or metatarsophalangeal joints or affecting other parts of the extremities, face, neck, or trunk; usually bilateral, symmetric, and almost always including similar changes in the digits
Minor Criteria	
Sclerodactyly	Sclerodermatous skin changes limited to the digits
Digital pitting, scars, or loss of substance from the finger pad	Depressed areas at the tips of digits or loss of digital pad substance from the finger pad tissue as a result of digital ischemia rather than trauma or exogenous causes
Bibasilar pulmonary fibrosis	Bilateral reticular pattern of linear or lineonodular densities that are most pronounced in basilar portions of the lungs on standard chest roentgenogram; may assume appearance of diffuse mottling or "honeycombing lung" and should not be attributable to primary lung disease

Classification as definite systemic sclerosis requires the presence of the major criterion or two or three of the minor criteria. From D'Cruz DP, Khamashta MA, Hughes GR. Systemic lupus erythematous. *Lancet*. 2007;369:587–596.

CLINICAL PRESENTATION

Patients with scleroderma most commonly present to the ED because of painful fingers due to Raynaud phenomenon, dyspnea due to restrictive lung disease, or dysphagia due to esophageal dysfunction. Malignant hypertension due to scleroderma renal disease is a true emergency.

Raynaud phenomenon is present in virtually all cases of scleroderma and is the initial manifestation in 70% of cases. Skin involvement is usually first manifested as edema of the fingers. As the disease progresses, the skin becomes shiny and taut with loss of the normal skin folds. Joints become immobilized from tight encasement in thickened skin and from contractures of muscles, tendons, and palmar fascia.

DIFFERENTIAL DIAGNOSIS AND ED EVALUATION

Established scleroderma causes a characteristic taut, smooth appearance of the hands and face. This sign should be apparent to the physician, although the patient may not have noticed the gradual changes.

Early disease may be difficult to recognize, however. The most common early symptom is painful fingers caused by Raynaud phenomenon, but this symptom is a nonspecific feature of many autoimmune disorders that may also be caused by occlusive arterial disease, repetitive trauma to the fingers, cryoglobulinemia, neurogenic lesions, or vasospastic drugs. Raynaud phenomenon unassociated with scleroderma is extremely common in women. Specific autoantibody testing may distinguish early cases of scleroderma from other causes of Raynaud phenomenon. Radiography of the hand may also be helpful. Subcutaneous calcinosis and resorption of the tufts of the distal phalanges are pathognomonic findings. More than 90% of patients with scleroderma have a positive ANA test.

An awareness of the systemic manifestations of disease is important in the evaluation of the patient with known scleroderma. Systemic collagen deposition may result in cardiac conduction abnormalities or cardiomyopathy, restrictive lung disease and pulmonary hypertension, gastrointestinal dysmotility and malabsorption, and renal arteriolar necrosis leading to malignant hypertension. Recognition of these manifestations in patients with advanced illness is critical.

ED MANAGEMENT

The majority of patients with Raynaud syndrome do not have symptoms requiring treatment in an ED. Patients with persistent vasospasm may respond to simple interventions, such as warming of the hands or oral administration of nifedipine. Only rarely are more invasive maneuvers, such as interarterial or local phenoxybenzamine or prazosin, required.

Systemic manifestations may require evaluation for dysfunction caused by scarring in many organ systems. Intestinal hypomotility

may be treated with metoclopramide. Esophageal reflux should be treated with antireflux maneuvers and medications as necessary. Patients with increased blood pressure, renal failure, and internal organ involvement are frequently treated with angiotensin-converting enzyme inhibitors.

DISPOSITION

Most patients with scleroderma do not require hospitalization, but admission may be necessary for dehydration due to gastrointestinal dysfunction or for pulmonary compromise. Patients with hypertensive emergency caused by renal crisis should be placed on nitroprusside and admitted to an intensive care unit. Patients with pulmonary artery hypertension can be treated with the endothelin receptor antagonist bosentan, which also has been shown to decrease the incidence of digital ulcerations in scleroderma (19).

Only those women with severe Raynaud phenomenon and those men without a history of trauma to the hands require periodic monitoring for the development of scleroderma. Patients should be instructed in the importance of keeping the hands warm and avoiding nicotine and caffeine. Suppressive pharmacologic therapy may be necessary if attacks are frequent.

Patients with signs and symptoms beyond Raynaud phenomenon should be referred for diagnostic autoantibody testing, occupational therapy, or orthopedics.

Common Pitfalls

- Failure to consider the systemic manifestations of scleroderma.
- Failure to recognize scleroderma as the cause of a hypertensive emergency.

GIANT-CELL ARTERITIS

Giant-cell arteritis is characterized by inflammation of branches of the carotid artery (temporal arteritis) or the aortic arch (Takayasu arteritis) and can present with emergent manifestations.

CLINICAL PRESENTATION

Temporal arteritis usually occurs in women older than 50 years. Symptoms may be nonspecific: Fever, headache, myalgias, and fatigue. Patients may have the syndrome of polymyalgia rheumatica, manifested by chronic stiffness and aching of the neck, shoulder, and hip girdle. There is frequent vestibular dysfunction and hearing loss at presentation (20). Chronic or subacute headache is often the presenting complaint.

The temporal artery may be tender and nodular (21), and there may be jaw claudication. The chief complication of temporal arteritis is monocular visual loss caused by ischemic optic neuritis. Visual loss or impairment generally occurs 3 or 4 months after the onset of initial symptoms (22).

Takayasu arteritis has a predilection for involvement of branches of the aortic arch. It is a rare disease. Patients are usually young women who present with nonspecific symptoms of fever, night sweats, fatigue, myalgias, and weakness. Signs of large vessel occlusion with decreased peripheral pulses, cerebrovascular accidents, or myocardial ischemia occur only months to years after initial presentation (23).

DIFFERENTIAL DIAGNOSIS AND ED EVALUATION

The differential diagnosis of patients with temporal arteritis is wide because of the nonspecific symptoms. Mild anemia is typical. A markedly elevated ESR in a patient older than 50 with headache and nonspecific symptoms, particularly polymyalgia rheumatica, should prompt further evaluation.

Takayasu arteritis, although rare, should be considered in any young female with signs of large vessel ischemia (e.g., cerebrovascular accident, upper extremity ischemia, cardiac ischemia).

ED MANAGEMENT AND DISPOSITION

Patients with suspected temporal arteritis rarely need admission to the hospital. Prompt diagnosis and treatment are essential to

prevent visual impairment. In the ED, patients should be started on 40 to 60 mg of prednisone daily. Arrangements should be made for definite follow-up and semi-urgent temporal artery biopsy. Response to corticosteroid treatment is usually dramatic, with relief of systemic symptoms and headaches within days. Treatment is generally continued for 1 to 2 years.

The diagnosis of Takayasu arteritis is not usually made in the ED. The diagnosis should be entertained in young women who need admission for large vessel occlusive disease. Angiography of the affected vessels shows narrowing or occlusion of large vessels with well-developed collateral circulation (24). Recent advances in computed tomography (CT) and magnetic resonance angiography (MRA) make these modalities important in evaluating the great vessels in patients (25). No treatment has been proven effective, but corticosteroids, cyclophosphamide and Tocilizumab an interleukin-6 inhibitor have been used.

Common Pitfalls

- Failure to consider temporal arteritis in an elderly patient who presents with headache or shoulder and neck stiffness.
- Failure to consider Takayasu arteritis in a young woman with signs of large vessel occlusion.

CRITICAL INTERVENTIONS

- Perform a diagnostic arthrocentesis to rule out infection or crystal-induced arthritis in patients presenting with new-onset monoarthritis or oligoarthritis.
- Treat cervical spine trauma in the RA patient carefully because of the development of instability of the atlantoaxial joint.
- Initiate corticosteroid therapy in the ED in the patient suspected of having temporal arteritis.

SECTION XIX
Infectious Disease Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 179

Bacteremia, Sepsis, and Septic Shock

Nathan I. Shapiro

Bacteremia is defined as the presence of viable bacteria in the blood. Bacteremia can be transient, which is commonly seen after injury to mucosal surfaces (e.g., from tooth brushing, urethral catheterization, sigmoidoscopy, etc.). In these cases, the intact host defenses neutralize the bacteria and their harmful products, preventing clinically significant manifestations of infection. In other situations, bacteremia triggers an activation of the inflammatory cascade, causing a condition known as sepsis. Sepsis is characterized by a host response to an infectious stimulus via endogenous mediators of systemic inflammation. In sepsis, the host response is as important as the source of infection in terms of pathophysiology and disease severity. Historically, definitions of sepsis have been diverse.

To promote uniformity of inclusion criteria in sepsis clinical trials, consensus conference definitions of sepsis were published by the American College of Chest Physicians and the Society of Critical Care Medicine in 1992 (Table 179.1) (1). The consensus conference definitions introduced the term *systemic inflammatory response syndrome* (SIRS). Indicators of systemic inflammation (SIRS criteria) are defined as the presence of two or more of the following conditions: (a) temperature $>38^{\circ}C$ or $<36^{\circ}C$, (b) heart rate >90 beats per minute, (c) respiratory rate >20 breaths per minute (or a $PaCO_2$ <32 mm Hg), or (d) white blood cell count $>12{,}000/mm^3$ or $<4{,}000/mm^3$ (or $>10\%$ band forms). The consensus conference also defined the terms *sepsis, severe sepsis,* and *septic shock*. *Sepsis* is

defined as two or more SIRS criteria in the presence of a known or presumed infection. *Severe sepsis* is defined as sepsis plus acute organ dysfunction attributable to sepsis. *Septic shock* is defined as profound sepsis-induced hypotension (systolic blood pressure [SBP] <90 mm Hg or a drop >40 mm Hg) accompanied by hypoperfusion abnormalities such as oliguria, acidosis, or alteration of mental status that is refractory to intravascular volume expansion (1). Although the SIRS classification is important from a research and epidemiologic perspective, the SIRS criteria are often overly sensitive and nonspecific in the emergency department (ED) setting and convey no incremental mortality risk. An increasing number of dysfunctional organs and septic shock are associated with increased mortality (2).

TABLE 179.1
Definitions

Systemic Inflammatory Response Syndrome (SIRS)

The physiologic response to a variety of severe clinical insults manifested by two or more of the following:

A. Temperature >38°C or <36°C

B. Heart rate >90 beats/min

C. Respiratory rate >20 breaths/min or a $PaCO_2$ <32 mm Hg

D. White cell count >12,000 cells/L, <4,000 cells/L, or >10% immature (band) forms.

Sepsis

The systemic response to infection manifested by the presence of SIRS.

Severe Sepsis

Sepsis associated with organ dysfunction or hypoperfusion. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status.

Septic Shock

Sepsis with hypotension (systolic blood pressure <90 mm Hg) despite adequate fluid resuscitation, along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status.

Multiple Organ Dysfunction Syndrome (MODS)

Presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention.

Adapted from American College of Chest Physicians, Society of Critical Care Medicine, Consensus Conference. Definitions of sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. *Crit Care Med*. 1992;20:864–874.

Angus et al. (3) utilized international classification of diseases (ICD-9) codes for infection and acute organ dysfunction to estimate that 751,000 severe sepsis cases occur in the United States every year. An ED-based epidemiologic study estimated 571,000 cases of severe sepsis present to the ED annually. The incidence of sepsis cases is projected to increase sharply in the future because of age-based shifts in the demographics of patient populations.

In large clinical trials of septic shock, control arm mortality rates have ranged from 24% to 60% (4–6). Although septic shock mortality reportedly decreased from the 1960s to the 1990s, an increase in mortality (1.5% per year) has been observed since 1995 (7). This increase has been attributed to the emergence of multidrug resistant organisms, increasing numbers of immunosuppressed

patients, and an age-based shift in the demographics of sepsis patients. With advances in cardiovascular and respiratory support of high-severity patients, the major threat to survival is not a sudden decompensation or a specific complication but a process of progressive failure of multiple organs. This process has been termed *multiple organ dysfunction syndrome* and is the major cause of death in patients with severe sepsis and septic shock.

CLINICAL PRESENTATION

Bacteremia is usually found in association with an acute illness and symptoms of fever, chills, and general illness forming the so called toxic state. Bacteremia and sepsis are dynamic processes in which the observed clinical manifestations depend on the point in the disease course the patient presents and the degree that the body's immune system and inflammatory cascade have been activated. Patients who progress to sepsis typically present with signs of systemic inflammation including fever, tachycardia, tachypnea, or elevated white blood cell count. Not all patients have a classic presentation or dramatic inflammatory response such as the elderly and the immunocompromised. The ED presentation of sepsis is not always clinically apparent in the initial stages. Because sepsis can be devastating, the ED physician must maintain heightened awareness and index of suspicion when evaluating patients with suspected bacteremia or sepsis.

Patients who progress to severe sepsis (sepsis plus organ failure) develop one or more organ dysfunctions including neurologic, respiratory, renal, hepatic, metabolic (acid–base), hematologic, or cardiovascular dysfunction. Central nervous system dysfunction typically presents as lethargy or acute alteration of mental status. Respiratory system dysfunction may include acute hypoxemic respiratory failure from acute lung injury/acute respiratory distress syndrome (ALI/ARDS). Acute renal insufficiency is common and may progress to oliguric renal failure. Cholestasis is the most common sign of hepatic dysfunction. Metabolic derangements include hyperglycemia and severe metabolic acidosis (usually from elevated lactate levels). Hematologic manifestations include a consumptive

coagulopathy, which is typically subclinical (8) but may present initially with thrombocytopenia and progress to disseminated intravascular coagulation (DIC).

The cardiovascular manifestations of sepsis are numerous, for septic shock is the most complex of all shock profiles. In septic shock, three different components of shock etiology may be occurring at the same time, especially during acute phase ED management (9). Septic shock may have features of cardiogenic shock (secondary to cytokine-induced myocardial depression), hypovolemic shock (secondary to profound capillary leak), or distributive shock (secondary to vasodilation). Because the proinflammatory response in sepsis causes diffuse microvascular injury with capillary leak, the septic shock patient often has a markedly decreased cardiac preload, especially in the initial phases of ED resuscitation. Although septic shock is typically considered a high–cardiac output vasodilatory shock (“warm shock”), the combination of myocardial depression and markedly decreased preload in the early hours of disease presentation cause the early stages of sepsis to sometimes manifest a low cardiac output (“cold shock”).

Fluid resuscitation administered in the acute phase of therapy actually modulates the hemodynamic profile of septic shock (9). Only after achieving restoration of cardiac-filling pressures with aggressive intravascular volume expansion will a septic shock patient be able to generate a high cardiac output. Despite cytokine-induced depression of the cardiac ejection fraction, a high cardiac output can be generated (after restoration of cardiac-filling pressures) because of tachycardia and ventricular dilation. Hypoperfusion abnormalities in septic shock may persist despite a normal or high cardiac output caused by marked peripheral vasodilation and alterations in blood flow distribution to the tissues (distributive shock) (10). The hallmark of septic shock is vasodilation (low systemic vascular resistance), causing arterial hypotension that requires vasopressor support. At the microcirculatory level, tissue perfusion abnormalities may exist in the absence of arterial hypotension and may manifest as lactic acidosis in normotensive sepsis (11).

DIFFERENTIAL DIAGNOSIS

The clinical signs of bacteremia and sepsis may be subtle and difficult to detect. In other instances, infection and systemic inflammation may be obvious, but the source of the infection may be difficult to identify. Although an inflammatory response is often caused by a bacterial infection, other possible etiologies must be considered. Acute infections caused by viruses, rickettsiae, mycobacteria, and parasites may present as acute "sepsis," but severe infection caused by these organisms is less common than that caused by bacteria. Early diagnosis of sepsis requires an awareness of specific predisposing host factors.

In addition to identifying the presence of a bacterial infection, one needs to localize the source of infection (i.e., pulmonary, intra-abdominal, skin, urogenital, or cerebrospinal fluid) and determine the most likely organism(s). This knowledge will help guide therapy, including source control and antibiotic selection. Consideration must be given to a wide variety of host factors that may alter the spectrum of probable organisms such as recent hospitalization or an immunocompromised state (HIV, chemotherapy, elderly, diabetes, etc.).

Diagnoses such as pancreatitis, congestive heart failure, adrenal dysfunction, hypothalamic injury, overdose, diabetic ketoacidosis, anaphylaxis, heat exhaustion, and neuroleptic malignant syndrome may mimic the inflammatory response seen with sepsis.

Although an elevated temperature often represents infection, at times it may be misleading. Hyperthermia and heat stroke may mimic many of the cardiopulmonary and neurologic manifestations of sepsis. Chills are not expected with heat stroke. Identification and confirmation of a source of infection through history, physical examination, laboratory testing, and radiologic studies can help narrow the differential.

The recognition of the shock state is essential in the approach to the septic patient. Patients with an SBP <90 mm Hg with accompanying evidence of tissue hypoperfusion (e.g., encephalopathy, acidosis, oliguria/renal insufficiency, poor skin perfusion, etc.) after an initial fluid challenge are considered to be in

shock. In septic shock, although initially a low–cardiac output "cold shock" state may be observed, the patients are classically (post resuscitation) in a hyperdynamic state with warm extremities and tachycardia. Cardiogenic shock patients tend to have cool extremities as a result of a compromised cardiac output and may show signs of cardiac ischemia through complaints of chest pain, shortness of breath, or an acute injury pattern on electrocardiogram. Hemorrhagic shock patients will typically have evidence of low hemoglobin concentrations, a source of blood loss, and cold and clammy extremities accompanied by flattened neck veins, tachycardia, and the absence of infectious symptoms. Patients with anaphylactic shock can typically be identified by an urticarial rash, pruritus, bronchospasm, throat tightness, and a history of exposure to a known allergen. Patients with neurogenic shock caused by spinal cord injury should be easy to identify by evidence of paralysis. Assessing the etiology of the patient's shock state is critical for guiding clinical management.

One must consider a broad differential in determining the presence of an infection, whether it is bacterial, viral, parasitic, or otherwise. In assessing the response to infection to determine whether it is sepsis, many other diagnoses need to be entertained. Once a shock state is reached, assessing the presence or absence of characteristic findings of the various shock profiles may help to determine the etiology of the shock.

ED EVALUATION

Because sepsis may progress rapidly, the ED evaluation must be expeditious. Appropriate stabilization measures are often carried out simultaneously with assessment. Vital signs must be reviewed. Unexplained tachycardia or tachypnea may be early clues to infection. Oral temperatures do not always accurately reflect core temperature. Rectal temperature measurement is recommended in any patient with suspected hypothermia or fever.

The physical examination should concentrate on potential sources for sepsis including lungs, abdomen, urinary system, central nervous system, and skin as the most common locations. Violation of a

mucosal or cutaneous barrier carries the risk of sepsis. All indwelling catheters and lines are possible sources of infection.

A wide variety of laboratory and ancillary tests are potentially useful in assessing the septic patient, but the following basic tests usually yield the most information: chest radiograph; serum electrolytes, glucose, blood urea nitrogen, and creatinine determinations; complete blood cell count, including white blood cell count and differential; urinalysis; blood cultures; and cultures of overt foci of infection. A serum lactate level helps to assess severity of illness and to predict risk (12).

Many of the patients who present to the ED with fever and possible sepsis have localizing signs or symptoms, which identify a focal infection. More difficult to assess are those patients without localizing signs or symptoms. One study found temperature >101°F, indwelling vascular catheter, clinical suspicion of endocarditis, age >65 years, chills, vomiting, hypotension, neutrophils >80%, white blood count >18,000 cells/mm^3, bands >5%, platelets <150,000 cells/mm^3, and creatinine >2 mg/dL to be associated with an increased prevalence of bacteremia (Table 179.2) (13). Applying the rule was shown to be 98% sensitive and 29% specific in a derivation set and 97% sensitive and 29% specific in a validation set.

TABLE 179.2
Presence of Bacteremia in Adults Presenting to the Emergency Department with Suspected Infection

Major Criteria:		Minor Criteria: (1 Point Each)
Suspect endocarditis	(3 points)	Temp 101–102.9°F (38.3–39.3°C)
Temp >103°F (39.4 °C)	(3 points)	Age >65 yr
Indwelling vascular catheter	(2 points)	Chills
		Vomiting
		Hypotension (systolic blood pressure <90 mm Hg)
		Neutrophils >80%
		White blood cells >18,000 cells/mm^3
		Bands >5%
		Platelets <150,000 cells/mm^3
		Creatinine >2 mg/dL

Decision rule: Either 1 major criterion or 2 or more minor criteria is an indication to obtain a blood culture. If these criteria are not present, a blood culture is not indicated by the rule.

Assessing patients for severity of illness and risk of mortality is always difficult, especially in the ED. A number of scoring systems have been created for this purpose in the intensive care unit (ICU) patients, including the APACHE-II, SOFA, MODS, and MPM-II scores. There is one scoring system specifically derived and validated in the ED setting for patients with suspected infection, the mortality in emergency department sepsis (MEDS) score. The MEDS score was created to identify patients at increased risk of death among ED patients presenting with possible infection. The components of the rule and scoring system are shown in Table 179.3. The different risk factors are "red flags" that should be sought to identify ED patients who are at increased risk of death during their hospital admission (14).

TABLE 179.3
Mortality in Emergency Department Sepsis Rule

Variable	Odds Ratio	95% CI	Points
Terminal illness (<30 d predicted mortality due to underlying illness—e.g., end stage CA, AIDS)	6.1	(3.6–10.2)	6
Tachypnea (RR >20 breaths/min) or hypoxia (pox <90%)	2.7	(1.6–4.3)	3
Septic shock (SBP <90 mm Hg after fluid challenge)	2.7	(1.2–5.7)	3
Platelets <150,000/mm^3	2.5	(1.5–4.3)	3
Bands >5%	2.3	(1.5–3.5)	3
Age >65 yr	2.2	(1.3–3.6)	3
Lower respiratory infection	1.9	(1.2–3)	2
Nursing home resident	1.9	(1.2–3)	2
Altered mental status	1.6	(1–2.6)	2
Mortality Estimates:			
Mortality Risk	**Points**		**Mortality**
Very low	0–4		0.9%
Low	5–7		2%
Moderate	8–12		7.9%
High	13–15		20%
Very high	>15		50%

MEDS score used to identify ED patients with suspected infection at increased risk of death. Mortality estimates are determined using a point system derived from the clinical variables.
RR, respiratory rate; SBP, systolic blood pressure.

ED MANAGEMENT

Stabilization often begins before assessment is complete. Careful attention to the basic principles of the ABCs of emergency medicine resuscitation is essential (airway, breathing, and circulation). One should have a low threshold for intubation. Wheeler and Bernard reported that 85% of patients with severe sepsis are ultimately intubated. Early intubation not only protects the airway but also reduces work of breathing and improves oxygen delivery (15). Adequate intravenous (IV) access should be ensured, cardiac monitoring should be instituted, and fluid resuscitation should begin. Early and aggressive resuscitation to reduce tissue hypoxia and organ dysfunction, coupled with appropriate antibiotics or surgical intervention, is warranted to reduce subsequent morbidity and mortality.

KEY TESTING

Laboratory testing:

- Complete blood count with differential (assess for leukopenia or leukocytosis, low hematocrit and adequate platelets, bandemia for immature cells)
- Basic chemistry
- Serum lactic acid level (for risk stratification)
- Consider liver function tests to assess for organ dysfunction or a gall bladder source of infection
- Urinalysis and culture as indicated
- Cerebrospinal fluid analysis as indicated

Radiology (guided by presentation)

- Chest x-ray
- Ultrasound or CT, based on potential focus of infection
- Cardiac echo as indicated

Fluids

Almost all patients with sepsis require IV volume expansion. The amount and rate of IV fluid infusion are guided by assessment of the patient's volume and cardiovascular status. Because of peripheral vasodilation and capillary leakage that are seen with sepsis, large quantities of fluid may be required to support the circulation. Volume administration may be best guided by observing the response of the central venous pressure (CVP) or pulmonary artery wedge pressure to aliquots of fluid given over a short period of time. In the absence of CVP monitoring, if there is a concern of causing pulmonary edema with aggressive intravascular volume expansion, fluid administration should be titrated using continuous pulse oximetry. Fluid administration is continued and slowed down when the supplemental oxygen requirement begins to increase.

It is important to maintain an aggressive fluid resuscitation in the elderly or those with a history of congestive heart failure. These patients require careful monitoring as the fluids are administered. Colloids (albumin, hetastarch) have no proven benefit over crystalloids (normal saline or Ringer lactate) in resuscitation (16).

Rivers et al. demonstrated the benefits of aggressive and goal-directed resuscitation of the septic patient in a randomized, double blind, placebo controlled trial (see Chapter 4, Shock). They used a combination of CVP monitoring, arterial blood pressure monitoring, and continuous measurement of mixed venous saturation from the superior vena cava ($ScvO_2$) to guide an aggressive ED resuscitation protocol for patients with septic shock or normotensive patients with a serum lactate level >4 mmol/dL. By continuously optimizing preload, perfusion, and oxygen delivery in the first 6 hours of a patient's care, mortality was reduced by 16% (absolute risk reduction).

The goal-directed protocol brings ICU level care into the ED and mandates an early resuscitation targeted to meet specific end points. Figure 179.1 summarizes the protocol. It normalizes preload by mandating a CVP of 8 to 12 mm Hg and corrects preload with fluid boluses if the CVP is low. Perfusion pressure is corrected with vasopressors and afterload reduction to obtain a mean arterial pressure between 65 and 90 mm Hg. Once preload and perfusion are normalized, the $ScvO_2$ is checked as a marker of tissue hypoxia. If preload and perfusion are normalized, and the $ScvO_2$ <70%, the patient is considered to be in a state of tissue hypoxia. This problem is addressed by first assuring that the patient has adequate oxygen carrying capacity (hematocrit >30%). If the hematocrit is low, the early goal directed therapy (EGDT) protocol calls for the patient to be transfused packed red blood cells. If the patient has adequate oxygen carrying capacity, and the $ScvO_2$ <70%, the EGDT protocol calls for dobutamine to improve cardiac output. Once all goals are met (ideally within the first 6 hours), the patient parameters are continuously monitored to ensure they stay in the normal range. A more recent randomized trial by Jones et al. demonstrated that the use of lactate clearance >10% was noninferior to $ScvO_2$ <70% as an endpoint of resuscitation. This supports the use of lactate clearance as an alternative endpoint (17). Treatment beyond the airway control and fluid resuscitation has four components: (a) parenteral

antibiotics, (b) removal or drainage of infected foci, (c) vasopressors, and (d) adjunctive therapies (e.g. steroids).

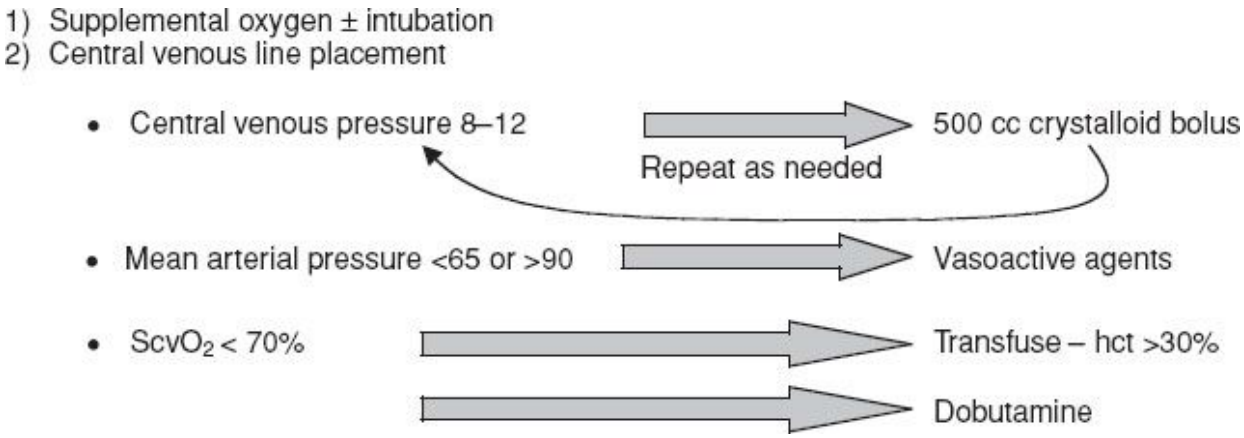

FIGURE 179.1 Summary of goal-directed therapy protocol.

Antibiotics

Initial parenteral antibiotics should be administered early in the ED course. Selection of particular agents is empiric, based on assessment of the patient's underlying host defenses, potential sources of infection, and probable responsible organisms. Antibiotics must be "broad-spectrum," covering both gram-positive and gram-negative bacteria, because both classes of organisms produce an identical clinical picture (Table 179.4).

TABLE 179.4
Antibiotic Regimens in Patients with Sepsis

	Modifying Factors	Antibiotic
Sepsis unknown source	Immunocompetent	Ceftriaxone (2 mg q12h IV) or Pipercillin (3 g q4h IV) or Imipenem (0.5 g q6h IV) or Meropenem (1 g q8h IV)
	For better *Pseudomonas* sp coverage	*plus* Gentamicin (2 mg/kg load then 1.7 mg/kg q8h IV)
	Immunocompromised (includes neutropenia and burns)	Pipercillin (3 g q4h IV) *plus* Gentamicin (2.0 mg/kg load then 1.7 mg/kg q8 h IV) or Ceftazidime (2 g q8h IV) *plus* Vancomycin (1 g q12h IV)
	Recent hospitalization or institutionalized	Add Vancomycin (1 g q12h IV) to the above regimen
Abdominal infection	Immunocompetent	Ampicillin (30 mg/kg q4h IV), *plus* Gentamicin (2 mg/kg load then 1.7 mg/kg q8h IV), *plus* Metronidazole (1.0 g q12h IV)
IV catheter infection (remove catheter)	Outpatient acquired MRSA suspected	Ceftriaxone (2 mg q12h IV) *plus* Vancomycin (1.0 g q12 h IV)
IV drug abuse	MRSA not suspected	Nafcillin (2 g q4h IV) *plus* Gentamicin (2 mg/kg load then 1.7 mg/kg q8h IV)
	MRSA suspected	Vancomycin (1 g q12h IV) *plus* Gentamicin (2 mg/kg load then 1.7 mg/kg q8h IV)

IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*.

For immunocompetent patients with an unknown source of sepsis, administer a single antibiotic with broad spectrum coverage such as ceftriaxone, piperacillin, imipenen, or meropenem. Immunocompetent patients with a suspected abdominal source of sepsis should receive ampicillin, gentamicin, and metronidazole or equivalent coverage from alternative antibiotics. A single broad-spectrum antibiotic is possible for immunocompromised septic patients, but most clinicians administer two broad-spectrum antibiotics with overlapping coverage (piperacillin plus gentamicin, or ceftazidime plus vancomycin). Septic patients who have had a recent hospitalization or are coming from a medical facility should receive vancomycin in addition to the other antibiotic coverage.

Patients with a history of IV drug abuse or those with indwelling catheters must also have appropriate antistaphylococcal coverage. Antipseudomonal coverage is critical in patients with neutropenia or burn sepsis.

Within these general guidelines, no one combination of antibiotics is clearly superior to another. The early and appropriate use of antibiotics has been shown to improve mortality (17). Failure to include adequate antibiotic coverage for the causative organism has been associated with an increased mortality risk.

Vasoactive Agents

If the patient's blood pressure does not respond to several liters of isotonic crystalloid (usually 4 L or more), despite an adequate preload being achieved (i.e., CVP 8 to 12 mm Hg), vasopressors are necessary. Several different agents (including norepinephrine, dopamine, phenylephrine, and vasopressin) are used to effectively achieve the blood pressure targets in septic shock (Table 179.5).

TABLE 179.5
Vasoactive Drugs Commonly Used in Septic Shock

Vasoactive Agent	Typical Dose	Vasoconstriction	Inotropy	Chronotropy
Norepinephrine	2–30 µg/min	++	+	+
Dopamine	6–20 µg/kg/min	+ (low dose) ++ (high dose)	++	++
Phenylephrine	20–200 µg/min	++	0	0
Vasopressin	0.01–0.04 U/min	++	0	0
Dobutamine	2.5–10 µg/kg/min	0 (mild vasodilation)	++	++

The two drugs most commonly used for initial management of septic shock are dopamine and norepinephrine. A relatively recent randomized trial demonstrated that the two drugs yielded equivalent outcomes overall; however, dopamine tended to be discontinued due to tachycardia (18). Only the subset of patients placed on vasopressors due to cardiogenic shock showed an outcome benefit with norepinephrine, while the septic shock subgroup showed no outcome benefit. Given the rate of undesired tachycardia with

dopamine, the evidence supports norepinephrine as the first vasopressor of choice in sepsis. Dopamine would be an acceptable second choice. Alternatively, the use of a pure α-agonist agent (vasoconstrictor) such as phenylephrine will not cause or exacerbate tachycardia and will probably also achieve blood pressure targets. The increase in afterload on the heart without any augmentation of cardiac contractility may decrease cardiac output in a patient who already has myocardial depression (either sepsis-induced or pre-existing).

Vasopressin is an agent that is gaining a larger role in management of septic shock (19). Via vascular smooth muscle receptors, vasopressin is a potent vasoconstrictor. In septic shock, a relative deficiency of endogenous vasopressin may develop, and this deficiency is thought to contribute to the pathophysiology of vasodilatory shock in sepsis. Low-dose vasopressin infusion can produce a dramatic restoration of blood pressure in septic shock. Consensus recommendations regarding the use of vasopressin in sepsis advocate that the agent be administered to patients with septic shock refractory to other vasoactive drugs (i.e., when other agents fail to achieve blood pressure targets) (20). The agent should only be administered in low doses (0.01 to 0.04 U/min) to replace a relative deficiency of endogenous vasopressin.

Because of potent vasoconstriction, vasopressin should be avoided in patients with known atherosclerotic heart disease and should not be administered in high doses. The vasoconstriction can increase afterload on the heart, which may impair cardiac output, especially if the patient has poor cardiac contractility. There are multiple trials currently under way to investigate whether or not vasopressin administration in septic shock improves outcome.

Inotropic support may be required for the patient with septic shock. If septic myocardial depression is identified either by echocardiography or by low-mixed venous oxygen saturation, an inotropic agent may be necessary. Although dobutamine is the most commonly used inotropic agent, it may cause mild vasodilation that could decrease blood pressure slightly. Administration of dobutamine may require some support from another vasoactive drug to safely

maintain blood pressure. As with dopamine, dobutamine may induce or exacerbate tachycardia to such an extent that diastolic-filling time and stroke volume decrease. Extreme tachycardia should be avoided if possible.

Adjunctive Therapy

The concept of corticosteroids as potent mediators of inflammation has been well explored in sepsis. There is theoretical and experimental support for the use of corticosteroids in severe sepsis and septic shock. Initially, a number of randomized human studies found that large doses of corticosteroids failed to prevent the development of shock, reverse the shock state, or improve the 14-day mortality. In a subsequent study Annane et al. were able to demonstrate a benefit of steroid supplementation in patients with adrenal suppression. However, a subsequent multinational, multicenter study of corticosteroids for severe sepsis patients (with an overall lower severity compared to the Annane trial) failed to show a mortality benefit. Steroids were more effective in reversing hypotension from presumptive adrenal suppression; however, there was an increase in secondary infection. While the data are still unclear, it is reasonable to consider steroid supplementation therapy in septic patients with hypotension refractory to vasopressors.

CRITICAL INTERVENTIONS

- Provide early airway management.
- Initiate aggressive fluid resuscitation.
- Identify the source of infection.
- Administer appropriate broad-spectrum antibiotics.
- Initiate aggressive resuscitation targeted to physiologic endpoints
- Fluid resuscitate to a CVP of 8 to 12 mm Hg.
- Start vasopressors for MAP <65 mm Hg after adequate initial fluid resuscitation.
- Transfuse to hematocrit $>30\%$ and initiate dobutamine if $ScvO_2$ $<70\%$.

DISPOSITION

The disposition of patients with a fever and no localizing signs of infection presents a dilemma. Otherwise healthy individuals who appear well and at low risk for occult bacterial infection can be discharged with instructions for fever control and a warning to return if symptoms persist or worsen. Patients who are elderly, have underlying immunodeficiency, or have disorders that predispose them to bacterial infection and other sepsis syndromes require a low admission threshold.

Given the 30% to 50% mortality for patients with septic shock and the benefit of intensive therapy, all patients with septic shock should be admitted to an ICU. Patients who are perceived to have high risk of developing septic shock, including normotensive patients with lactic acidosis, should be admitted to an ICU.

Common Pitfalls

- Failure to consider serious bacterial infection as a possibility in the evaluation of subtle signs and symptoms.
- Restriction of fluid resuscitation for fear of inducing pulmonary edema. Large quantities of fluid may be required in patients with sepsis.

CHAPTER 180 Skin and Soft Tissue Infections

Clifford Rice

FOLLICULITIS AND CUTANEOUS ABSCESS

CLINICAL PRESENTATION

Folliculitis is an inflammation of hair follicles due to infection, overhydration, chemical irritation, or physical injury of the skin (1). The most common sites of involvement are the apocrine areas of the upper back, chest, buttocks, hips, and axillae. However, folliculitis can occur in any hair-bearing region of the body. The most common infecting organism is *Staphylococcus aureus,* but streptococci and gram-negative organisms are implicated in many cases. Since the mid-1990s, community-acquired methicillin-resistant *S. aureus* (CA-MRSA) has become an increasingly common and important cause of skin infections and folliculitis (2). Other bacterial causes include *Pseudomonas aeruginosa,* which has been reported after exposure to hot tubs and ordinary baths and showers (2). The individual lesion of folliculitis is a 2- to 5-mm dome-shaped pustule with a central hair shaft surrounded by a rim of erythema. Superficial folliculitis is often primarily pruritic rather than painful and heals without scarring. If inflammation progresses deeper into the follicle, pain and tenderness develop, and scar formation is more likely to occur with healing.

Pseudofolliculitis is a foreign body reaction caused by close shaving in persons of African descent. It is a noninfectious, inflammatory condition that can affect both men and women. The hair shaft becomes trapped below the follicle exit and, because of its propensity

for tight curling, grows into the follicular wall. Sycosis barbae is a deep infectious progression of pseudofolliculitis that, if untreated, can lead to significant facial scarring.

An untreated follicular infection, or one that does not resolve on its own, can evolve into a *furuncle, abscess,* or *carbuncle.* A furuncle is an infection of the hair follicle that extends into the subcutaneous tissue where it forms a small abscess. The bacteriology is the same as that of folliculitis, including CA-MRSA. A carbuncle is formed by multiple interconnecting furuncles that drain through several skin openings. Common locations of carbuncles include the chin, back of the neck, and scalp.

Cutaneous *abscesses* can also originate in any part of the body through local breaks in the skin. While skin abscesses can develop in healthy individuals, patients with diabetes, immunologic disorders, and inflammatory bowels disease, as well as intravenous (IV) drug abusers are at greater risk compared to the general population. Pure *S. aureus* is cultured in common abscesses; streptococci, gram-negative organisms, and anaerobes are recovered in other cases, often as polymicrobial cultures (3,4). CA-MRSA has recently been reported to be responsible from 21% to 80% of skin infections and abscesses (2). Among prisoners in San Francisco, the occurrence of CA-MRSA has increased from 29% of cases in 1997 to 74% in 2002 (2).

Prevalence of CA-MRSA in emergency department (ED) patients has been found to be as high as 56% in purulent skin and soft tissue infections, almost all of which are the same type, USA-300 (5). These soft tissue infections can be found in healthy children and young adults and can be severe and even life threatening. Although some can be traced back to hospital MRSA (H-MRSA), most infections are arising in the community de novo. Unexpectedly, CA-MRSA is genotypically and phenotypically unrelated to hospital-acquired MRSA (4). Fortunately, few strains are multiply resistant to antibiotics. There are no clear clinical characteristics that help differentiate between CA-MRSA and H-MRSA infections. CA-MRSA infections tend to occur in clusters; therefore, cultures are important to obtain in a suspected outbreak. Also, multiple risk factors for CA-

MRSA have been cited in the literature, including incarceration, men who have sex with men, patients with multiple abscesses at the same time, and IV drug abuse, among others (5).

A cutaneous abscess presents as a red, painful, usually fluctuant mass. The patient typically experiences discomfort and swelling for several days before presentation for care. Systemic symptoms (fever, chills, tachycardia, and malaise) are unusual, but can occur if the abscess is extensive, is surrounded by significant cellulitis, or extends along a mucous membrane such as the rectum or oral cavity.

Cutaneous abscesses are frequently associated with other conditions. Hidradenitis suppurativa is a recurrent, suppurative, and scarring disease of the apocrine glands, most commonly involving the axillae and pubic regions of persons of African descent. Their greater concentration of apocrine glands leaves these persons more susceptible to infection from chemicals (deodorants, depilatories), trauma (shaving), or poor hygiene. Hidradenitis can be divided into acute and chronic phases. In the acute phase, when burning and itching predominate, single abscesses can develop. In the chronic phase, sinus formation and honeycombed scarring can be seen. Multiple and recurring abscesses are not uncommon.

Abscesses of the buttock and perineum can arise from multiple sources (3). An abscess in the proximal buttock crease is often associated with pilonidal disease. This condition generally afflicts hirsute young males, but its origins are unclear (1). Ingrown hair or, possibly, congenital remnants of hair follicles and squamous epithelium at the sacrococcygeal junction predispose to abscess formation.

When an abscess arises close to the anus, careful differentiation has to be made between a true perianal and a simple buttock lesion. Perianal abscesses originate from anal crypts, are very painful on rectal examination, and are often associated with systemic symptoms such as fever, malaise, and anorexia (4,6). If left untreated, they can dissect proximally into the ischiorectal space and become perirectal abscesses. Recurrent or persistent buttock and perianal abscesses can originate from fistulous tracts created by inflammatory bowel disease.

Bartholin gland abscess is a common problem that can arise from duct obstruction and infection with vaginal flora. The Bartholin glands are located within the vaginal vestibule at the 4 o'clock and 8 o'clock positions. A cyst or infection manifests as a mass medial to and often including the labia minor. The predominant organisms are anaerobic, including *Bacteroides fragilis* and peptostreptococci, and are associated with a variety of gram-negative enteric organisms in mixed culture (6). Of the identified aerobic organisms, *Neisseria gonorrhoeae* is the most important because treatment of these abscesses should include antibiotics for sexually transmitted diseases.

DIFFERENTIAL DIAGNOSIS

When considering folliculitis, the differential diagnosis includes acne vulgaris, impetigo, cutaneous fungal infections, skin infestations (scabies), insect bites, HIV-associated eosinophilic folliculitis, and viral disorders (herpesvirus). The lesions of a systemic bacterial infection (*P. aeruginosa* and *N. gonorrhoeae*) can appear like scattered follicular disease. Abscesses have to be differentiated from other nodular lesions, such as uninfected cutaneous cysts, malignant tumors, nodular fungal lesions, and foreign body granulomas.

ED EVALUATION

When assessing a patient for folliculitis, furuncles, or a cutaneous abscess, the most important differentiation is between those lesions that contain pus and those that do not. Whenever there is doubt, bedside ultrasound or needle aspiration can be used to differentiate between superficial induration and the presence of a localized subcutaneous fluid collection suggesting abscess (Fig. 180.1) (7). If pus is discovered, incision and drainage should follow. There is controversy as to whether at-risk patients and patients in communities with high CA-MRSA prevalence should routinely have wound cultures done or routinely receive antibiotics. Generally, these are not recommended unless there is surrounding cellulitis, systemic toxicity, or recurrent abscesses (8).

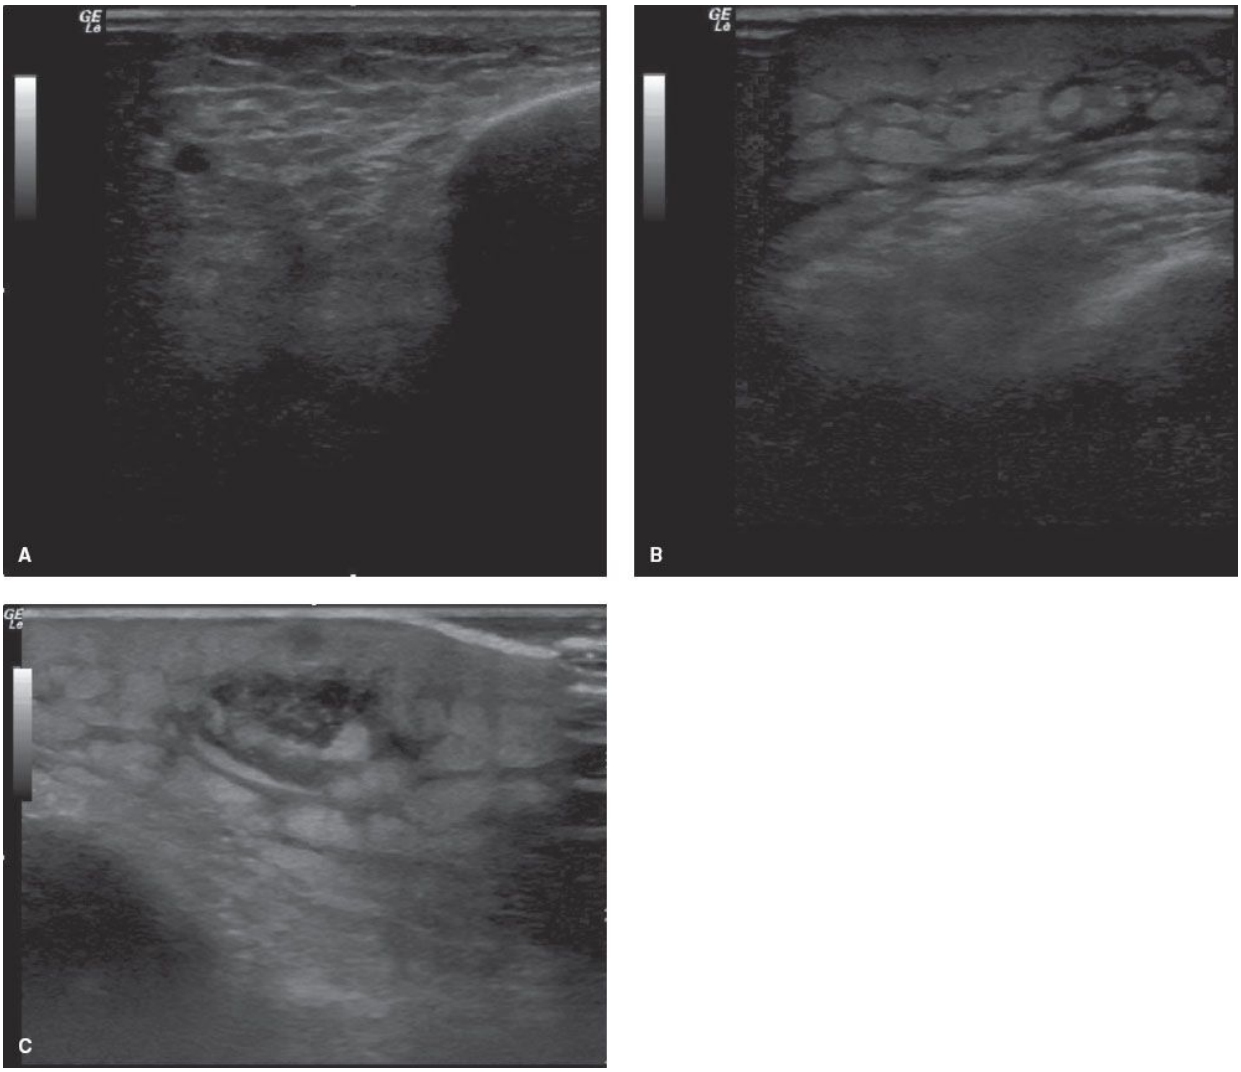

FIGURE 180.1 Ultrasound can be used in the arena of soft tissue infection to detect the presence or absence of localized fluid collections suggesting abscess. **A:** Ultrasound of normal superficial soft tissue. **B:** Ultrasound of cellulitis demonstrating the cobblestone appearance of the soft tissue when induration if present. **C:** Ultrasound demonstrating a well circumscribed fluid collection with surrounding cobblestoning seen in a patient with cellulitis with underlying abscess.

An assessment of underlying conditions is necessary to determine the overall risk to the patient. Patients with diabetes, immunosuppression, blood dyscrasia, altered white blood cell function, or valvular heart disease are at greater risk from cutaneous

infections. The presence of systemic signs such as malaise, fever, and tachycardia indicates a more widespread involvement of the cutaneous infection and requires a somewhat more extensive ED evaluation.

KEY TESTING

- Labs
  - Wound cultures in the presence of surrounding cellulitis, systemic toxicity, or recurrent abscesses
- Imaging
  - Bedside ultrasound to assess for subcutaneous fluid collection and help guide management

ED MANAGEMENT AND DISPOSITION

Treatment for folliculitis depends on the extent and depth of follicular involvement. For uncomplicated common folliculitis and hot tub folliculitis, removing the offending agent and a gentle regimen of once- or twice-daily skin cleansing with mild hand soap often suffices. This regimen can be supplemented by topical applications of antibiotics such as bacitracin and polymyxin B (Polysporin) or mupirocin (Bactroban). Pseudofolliculitis is managed by allowing the involved hair areas, usually on the face, to grow at least 2 to 3 mm above the surface. Special commercially available razors (PFB foil-guarded Remington and Norelco electric razors) are designed for people with this condition.

If the folliculitis is painful or more extensive and involves the deep portions of the follicle, a 5- to 7-day course of oral antibiotics is added to the aforementioned measures (Table 180.1). The risk of CA-MRSA has to be considered as well in the choice of antibiotics. Patients with recurrent folliculitis should seek follow-up for consideration of prophylactic measures, such as the prolonged administration of an oral clindamycin or intranasal mupirocin to eliminate an *S. aureus* carrier state (9).

TABLE 180.1
Oral Antibiotic Regimens for Adults with Uncomplicated Cutaneous Infections

Condition	Antibiotic	Dose	Interval
Erysipelas	Penicillin	500 mg	q6h
	Amoxicillin	500 mg	q8h
	Erythromycin	250 mg	q6h
MRSA	Clindamycin	300–450 mg	q6–8h
Furuncles, carbuncles, skin abscess, and purulent cellulitis (cellulitis with purulent drainage, with exudate, and without underlying abscess)	TMP-SMX	2 DS tabs	q12h
	Doxycycline	100 mg	q12h
	Linezolid	600 gm	q12h
Non-MRSA	Dicloxacillin	500 mg	q6h
Nonpurulent cellulitis	Cephalexin	500 mg	q6h
(Cellulitis without purulent drainage, without exudate, and without underlying abscess)	Clindamycin	300–450 mg	q6–8h
Empiric treatment for MRSA and β-hemolytic streptococci	Clindamycin	300–450 mg	q6h
Furuncles, carbuncles, skin abscess, and cellulitis	Amoxicillin *PLUS*	500 mg	q8h
	TMP-SMX	1 DS tab	q12h
	Amoxicillin *PLUS*	500 mg	q8h
	Doxycycline	100 mg	q12h
	Linezolid	600 mg	q12h
Hot tub folliculitis	Ciproflaxacin	250–500 mg	q12h
Impetigo	Mupirocin Ointment	Apply to affected area	q8h
Bartholin abscess	Ceftriaxone *PLUS*	250 mg IM	once
	Doxycycline	100 mg	bid

Untreated folliculitis can progress to a furuncle. If the furuncle has yet to suppurate, as demonstrated by the inability to obtain pus on needle aspiration, a regimen of warm soaks and antibiotics is recommended (Table 180.1). For the buttock and perineal area, warm soaks or sitz baths are recommended at least twice a day. Patients should be seen within 48 to 72 hours for follow-up, at which time surgical drainage can be performed if the furuncle has suppurated. Carbuncles are more likely to present as obvious suppuration that will require surgical drainage.

Incision and drainage are indicated for most cutaneous abscesses. Appropriate analgesia, sedation, and anesthesia should be provided. For most small superficial abscesses (<5 cm), local anesthesia of the

skin over the abscess usually suffices. For very small abscesses, ethyl chloride spray can be followed by immediate incision. Local anesthesia can be supplemented by administering a parenteral opioid before intervention. For large or deep abscesses or those located in particularly sensitive areas, such as the perineal region, consideration can be given to IV administration of short-acting sedative and analgesic agents with appropriate monitoring.

Before incision, the abscess is cleansed with povidone-iodine or a similar skin cleanser. The incision is made with a number 11 surgical blade attached to a knife handle. To provide for maximum drainage and access, the length of the incision should be at least two-thirds the diameter of the actual cavity to allow for digital or gentle instrument probing and disruption of loculations and pockets in the irregularly shaped cavity. Probing is followed by saline irrigation with a soft-tipped catheter attached to a syringe. Probing and irrigation are terminated when the effluent is pus-free and blood-tinged.

The cavity is lightly packed with gauze tape (one-fourth or one-half inch wide) to encourage further drainage. Excessive packing can result in obstruction of drainage. A bulky dressing is usually necessary to absorb continuing secretions. The packing can most often be removed at follow-up in 48 to 72 hours. This is followed by a regimen of warm soaks or sitz baths at least two times a day until drainage ceases. An abscess cavity takes 10 to 14 days to heal. Large abscesses take longer to heal and may need to be repacked once or twice at 48-hour intervals.

Special considerations apply to the management of Bartholin abscess. The incision is made on the medial portion of the abscess, close to the vaginal introitus, to avoid excessive bleeding. Instead of gauze packing, a small balloon-tipped (Word) catheter is recommended for drainage (10). This is followed by once- or twice-daily sitz baths. The catheter is left in place for 4 to 6 weeks to produce epithelialization of the incision and drainage site and to reduce the risk of abscess recurrence.

Early consultation should be considered for patients with facial, perianal, pilonidal, and Bartholin abscesses and infection secondary

to parenteral drug abuse. For cosmetic reasons, the approach to drainage of facial abscesses (e.g., needle aspiration, mucosal approach) should be discussed with a consultant. Perianal abscesses often require general anesthesia in an operative setting. Patients with pilonidal and Bartholin disease require appropriate follow-up because of the potential for recurrence. Soft tissue infections in parenteral drug users can be deceptively extensive and involve the deep soft tissue; affected patients are also at risk for systemic and cardiac valvular disease. They often require hospital admission for evaluation and treatment.

Ordinarily, simple, uncomplicated, cutaneous abscesses need not be treated with systemic antibiotics (11,12). Antibiotics are indicated for abscesses associated with fever, abscesses surrounded by a wide area of cellulitis, abscesses in which previous incision and drainage (I and D) has failed, and in high-risk patients (i.e., diabetics, immunocompromised patients).

If oral antibiotics are appropriate, treatment should cover both β-hemolytic streptococci as well as MRSA. Oral antibiotic options are clindamycin, trimethoprim-sulfamethoxazole plus a β-lactam, a tetracycline plus a β-lactam, or linezolid alone. If the infection is known to be CA-MRSA, the antibiotic options are: clindamycin, trimethoprim-sulfamethoxazole, a tetracycline, or linezolid (13) (Table 180.1).

If IV treatment is deemed necessary, wound cultures should be obtained, and antibiotic therapy should empirically cover CA-MRSA awaiting culture results. Parenteral antibiotic options include vancomycin, linezolid, daptomycin, telavancin, and clindamycin (15) (Table 180.2). Knowledge of local drug sensitivities is important because of wide variability across the country (2).

TABLE 180.2
Intravenous Antibiotic Regimens for Adults with Serious or Complicated Cutaneous Infections

Condition	Antibiotic	Dose	Interval
MRSA	Vancomyin	15–20 mg/kg	q8–12h
Furuncles, carbuncles, skin abscess, purulent cellulitis (cellulitis with purulent drainage, with exudate, and without underlying abscess), and necrotizing soft tissue infections	Daptomycin	4 mg/kg	q24h
	Linezolid	600 mg	q12h
	Telavancin	10 mg/kg	q24h
	Clindamycin	600–900 mg	q8h
Non-MRSA	Cefazolin	1–2 g	q8h
Furuncles, carbuncles, skin abscess, and nonpurulent cellulitis	Oxacillin	2 g	q4h
	Nafcillin	2 g	q4h
(Cellulitis without purulent drainage, without exudate, and without underlying abscess)	Clindamycin	600–900 mg	q8h
Necrotizing soft tissue infections	Piperacillin–tazobactam	3.375 or 4.5 g	q6h
secondary to gram-negative and anaerobic pathogens	Ticarcillin-clavulanate	3.1 g	q4h
(If MRSA a possibility add vancomycin)	Ceftriaxone *PLUS*	1 g	q24h
	Metronidazole	500 mg	q8h
	Ciprofloxacin *PLUS*	400 mg	q12h
	Metronidazole	500 mg	q8h

Manipulation of an abscess can cause bacteremia in 30% of cases but is most relevant in patients with pre-existing cardiac valve disease. These patients must be given adequate antibiotic prophylaxis, as recommended by the American Heart Association guidelines, before intervention (14,15). Antibiotic prophylaxis is reasonable for procedures involving infected skin, skin structures, or musculoskeletal tissue only for patients with underlying cardiac conditions associated with the highest risk of adverse outcome from infective endocarditis (IE) (15). Cardiac conditions associated with the highest risk of adverse outcome from IE include prosthetic cardiac valve or prosthetic material used for cardiac valve repair, previous IE, unrepaired cyanotic congenital heart disease (CHD), including palliative shunts and conduits, completely repaired congenital heart defect with prosthetic material or device (whether placed by surgery or by catheter intervention, during the first 6 months after the procedure), repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization) and cardiac transplantation recipients who develop cardiac valvulopathy. The antibiotic administered should be administered 30 to 60 minutes prior to the procedure and have activity against staphylococci and β-hemolytic

streptococci. Suitable choices include an antistaphylococcal penicillin or a cephalosporin (cephalexin 2 g PO). Vancomycin (1 g IV) or clindamycin (600 mg PO/IM/IV) may be administered to patients unable to tolerate a β-lactam or who are known or suspected to have an infection caused by a methicillin-resistant strain of staphylococcus (24).

Common Pitfalls

- Failing to perform needle aspiration or ultrasonography because an abscess is mistaken for a small area of cellulitis or a furuncle
- Making an abscess incision that is too small to permit adequate drainage
- Mistaking a perianal abscess for a buttock abscess
- Prematurely removing the Word catheter from a Bartholin abscess
- Failure to consider the possibility of cardiac conditions associated with the highest risk of adverse outcome from IE when performing a procedure on an infected skin structure and then providing antibiotic prophylaxis.
- Failing to consider CA-MRSA as the cause of cellulitis or abscess

CUTANEOUS CELLULITIS

CLINICAL PRESENTATION

Cellulitis is an acute, spreading infection of the deep dermis and subcutaneous fat characterized by pain, warmth, swelling, and erythema. It is most often caused by group A *Streptococcus* and *S. aureus* (9). CA-MRSA has also been shown to cause cellulitis (12). The first sign of common cellulitis is local skin discomfort, which is rapidly followed by frank tenderness, erythema, and swelling (16). Within 24 hours, there is noticeable expansion of the process, even though the margins themselves are indistinct. In spite of the progression, fever and chills occur in $<10\%$ of cases (16). Lymphangitic "streaking" that extends from the primary site proximally is a very specific and reliable diagnostic sign. In the

preantibiotic era, this progression was known as “blood poisoning” and not uncommonly led to death.

Erysipelas is an infection of the upper dermis and superficial lymphatics caused almost exclusively by group A streptococci, although occasional cases are due to *S. aureus*. Erysipelas is most common in infants and young children, but it occurs in adults as well (3). It can begin as a result of minor skin trauma, surgical intervention, or a pre-existing skin condition. In adults, it is likely to occur in the setting of venostasis, lymphedema, diabetes, or alcohol abuse. In contrast to common cellulitis, the lesion of erysipelas is sharply demarcated, indurated, and easily palpable. Characteristically, it is also shiny red. It is usually associated with fever and an elevated white blood cell count. Untreated lesions can form bullae that break down and leave raw, weeping surfaces.

A serious form of cellulitis formerly seen in children, and occasionally in adults, is caused by *Haemophilus influenzae* type B (HiB). Although most commonly involving the face and the periorbital tissues, HiB cellulitis can also involve the arms and legs. In adults, it may originate as a respiratory infection and then involve the neck and chest. In children, the cellulitis often takes on a blue-red to purple-red appearance. In both adults and children, HiB cellulitis is associated with systemic toxicity and a significant risk of sepsis and secondary site involvement. With the widespread vaccination of children against HiB, the rates of infection caused by this organism have fallen.

Aeromonas hydrophila and *Vibrio vulnificus* are two water-related organisms that can cause uncommon forms of cellulitis (17,18). The skin infection of *A. hydrophila* follows local trauma and exposure to fresh water; early infections are indistinguishable from streptococcal cellulitis but often progress to bullae, abscess formation, and foul-smelling exudate. *V. vulnificus* cellulitis occurs after trauma and exposure to salt water. The infection can range from mild cellulitis to an aggressive infection associated with vesicles, bullae, and myositis that can mimic gas gangrene.

DIFFERENTIAL DIAGNOSIS

Cellulitis can be difficult to distinguish from other cutaneous conditions. The most serious condition to be considered is thrombophlebitis, particularly when the lower extremity is involved. Cellulitis can be differentiated by the presence of fever, lymphangitic streaking, an advancing margin, and an elevated white blood cell count, although these findings are not consistently present.

Viral and drug-related exanthems can be localized but usually are associated with recognizable precipitants and specific syndromes.

Dermatitis can appear red and somewhat warm but is usually associated with considerable itching and scaling. Secondary infection of dermatitic lesions, however, is not uncommon.

Insect stings, particularly those due to *Hymenoptera,* can cause significant local reactions that can be confused with cellulitis, and these reactions can persist up to 7 days (19). As compared with cellulitis, insect stings produce more pain than tenderness, cause more edema and less erythema, and are pruritic.

Fungal infections of the skin, particularly with *Candida,* appear in characteristic locations (often intertriginous), have a distinctive appearance (moist, bright red), and can be identified by potassium hydroxide staining.

ED EVALUATION

Cellulitis and erysipelas localized to a small area in an otherwise healthy patient, needs no invasive or laboratory testing. With more extensive cellulitis, a white blood cell count is performed to check for signs of systemic involvement and to gauge the severity of infection. Because of the low bacterial count in the lesions of cellulitis, aspiration of the advancing margin for gram stain and culture is of little value. In any event, these tests do not aid in immediate treatment decisions.

In compromised hosts and in patients in whom *H. influenzae* infection is suspected, a more extensive workup is indicated. The incidence of bacteremia ranges from 5% in toxic streptococcal cellulitis to 90% in *H. influenzae* cellulitis. Gram stain and culture, though of low yield, can be performed in an attempt to identify the causative organism. Older patients and those with underlying

conditions such as diabetes or immunocompromised states should be evaluated for metabolic derangements and any evidence of other sites of involvement. Outlining the margins of the cellulitis with a marker can aid in the monitoring and follow-up of patients with cellulitis by indicating lesion progression or regression. In symptomatic patients, imaging including x-ray, CT, MRI, and ultrasound of the affected area can be useful in assessing for deeper infections and abscesses.

KEY TESTING

- Labs
  - CBC
  - Blood cultures in patients presenting with systemic toxicity
- Imaging
  - X-ray, CT, MRI, and bedside ultrasound can be used to help assess patients presenting with concern for deep space infections and abscesses

ED MANAGEMENT AND DISPOSITION

Localized cellulitis and mild, uncomplicated erysipelas in patients without risk factors can be treated as outpatients. Oral penicillin, amoxicillin, or erythromycin can be used to treat erysipelas. The selection of antibiotic therapy for cellulitis, according to the 2011 Infectious Disease Society of America guidelines, is steered by presence or absence of purulence (13). A purulent cellulitis is defined as a cellulitis with the presence of purulent drainage or exudate without an underlying abscess. A nonpurulent cellulitis is defined as a cellulitis without purulent drainage, exudate, or underlying abscess.

Patients with purulent cellulitis should be treated empirically for infection due to MRSA. Oral antibiotic choices include clindamycin, trimethoprim-sulfamethoxazole, a tetracycline, or linezolid (13).

Patients with nonpurulent cellulitis should be treated empirically for infection due to β-hemolytic streptococci and methicillin-susceptible *S. aureus* (MSSA) with a β-lactam. Patients not

responding to treatment with a β-lactam alone should have their antibiotic regimen change to include coverage for CA-MRSA (13). See Table 180.1.

Oral antibiotics are begun, and close (48- to 72-hour) follow-up is arranged. Duration of treatment ranges from 7 to 14 days. As a rule, antibiotics are continued for 3 days after the resolution of clinical findings. Resolution of cellulitis of the lower extremities can be slow because of dependency and associated edema (20). For this reason, strict elevation for several days is mandatory. If significant resolution has not occurred within 2 or 3 days, a brief hospitalization might be necessary.

Other indications for hospital admission and infectious disease consultation are the presence of signs of systemic toxicity; underlying illnesses such as diabetes; specific involvement of areas such as the face, orbit, hand, perineum, or extensive lower extremity (particularly with pre-existing edema); presumed *H. influenzae* infection; or suspected gram-negative organisms or mixed infections. Patients who require admission should be treated with broad spectrum IV antibiotics. Parenteral antibiotic options include vancomycin, linezolid, daptomycin, telavancin, and clindamycin (Table 180.2).

Common Pitfalls

- Failing to instruct patients about elevation and care of the involved area
- Misdiagnosing deep vein thrombosis as lower extremity cellulitis
- Failing to arrange follow-up in 48 to 72 hours for patients with cellulitis
- Unnecessarily treating insect stings with antibiotics
- Failing to appreciate deeper infection or underlying abscess

DEEP CUTANEOUS AND NECROTIZING SOFT TISSUE INFECTIONS

Deep cutaneous and necrotizing soft tissue infections are a group of disorders with many predisposing factors and a wide spectrum of

bacteria (21). Though early recognition and aggressive treatment are important ways of reducing an already high mortality, these infections can be deceptively benign in appearance (21). This benign presentation is no better illustrated than in group A streptococcal infections caused by streptococci, sometimes called “super strep,” that elaborate highly toxic super antigens (22). Patients with soft tissue involvement can complain of severe, disabling pain without skin or soft tissue changes. Early recognition of these infections before they evolve to full blown streptococcal toxic shock syndrome is important to reducing morbidity and mortality (see Chapter 192, “Toxic Shock Syndromes”).

CLINICAL PRESENTATION

Early in the clinical course, attempting to separate the various types of deep infections into discrete syndromes is made difficult by the fact that they share many characteristics. However, it is recognition of these characteristics that alerts the clinician to a potentially emergent condition.

1. These infections occur in settings that include trauma, foreign body penetration, contamination with soil, surgical intervention, ischemia, or diabetes.
2. Tissue involvement is extensive, but classic signs of common cellulitis (heat, redness, induration) are often not present.
3. As the infection progresses, blebs, maceration, and exudate appear.
4. The hallmark of these infections, though not always present, is crepitance secondary to gas formation.

Specific deep cutaneous infections are summarized in Table 180.3.

TABLE 180.3
Deep Cutaneous and Necrotizing Soft Tissue Infections

Characteristics	Crepitant Cellulitis	Synergistic Necrotizing Cellulitis	Necrotizing Fasciitis	Clostridial Cellulitis	Clostridial Myonecrosis
Predisposing conditions	Wounds, decubiti, peripheral vascular disease, diabetes	Diabetes, obesity, advanced age	Postoperative wounds, perianal infection, chronic cutaneous ulcers, intravenous drug use	Contaminated wound	Devitalized tissue, focal contamination
Onset	Gradual	Subacute, over several days	Variable, indolent to fulminant	Gradual, 4–5 d	Acute, 1–3 d
Pain	Mild	Severe	Minimal, sometimes hypesthesia	Mild	Severe, early
Systemic toxicity	Mild to moderate	Moderate to severe	Marked	Mild to moderate	Marked, early
Overlying skin	Minimal, discoloration brown to gray	Blue-gray, necrosis	Initially spared, then pale followed by gangrene	Minimal change, occasional blebs	Initially normal, then pale bronze discoloration followed by necrosis
Exudate	Minimal, dark	Thin, reddish brown ("dishwater pus")	Rare, serous	Thin, dark	Serosanguineous
Odor	Foul	Foul	Foul	Rarely foul	"Mousy," slightly sweet
Gas formation	Abundant	Mild, up to 25%	Little	Abundant	Initially minimal, eventually moderate
Muscle involvement	No	Prominent feature, moderate spread	Rare, late	No	Prominent
Common pathogens	Anaerobes, Enterobacteriaceae	*Bacteroides fragilis*, streptococci, Enterobacteriaceae	Enterobacteriaceae, streptococci, *Bacteroides*, peptostreptococci	*C. perfringens*, *C. septicum*, *C. novyi*	*C. perfringens*, *C. septicum*, *C. novyi*

From Brillman JC, Quinzer RW, eds. *Infectious Disease in Emergency Medicine*. Boston, MA: Little, Brown and Company; 1992:822–823.

Crepitant cellulitis occurs most commonly in the setting of pre-existing, lower extremity, peripheral arterial disease; decubitus ulcer; or a moderately severe traumatic wound. Also known as nonclostridial anaerobic cellulitis, this is a gas-forming infection that results from the synergistic interaction of anaerobic bacteria (*Bacteroides* species and peptostreptococci) and of gram-negative bacteria of enteric origin. In spite of its seriousness, it is usually gradual in onset, with mild local tenderness, and is not likely to cause serious systemic toxicity. In the area of involvement, the skin is minimally discolored and may appear grayish to brown, depending on local vascularity. The exudate, if present, is dark and foul smelling. The hallmark of this infection is crepitance and abundant gas formation, as seen on radiographs. The infection remains localized to the skin and subcutaneous tissues without extending to the muscle.

Synergistic necrotizing cellulitis has also been called nonclostridial gangrene and nonclostridial anaerobic myonecrosis. Fournier gangrene of the male genitalia and perineum is a variant of this condition. Synergistic necrotizing cellulitis occurs most often in older patients with serious underlying disease such as diabetes, congestive heart failure, or renal failure, and in the setting of obesity and perirectal infections. Gram-positive streptococci (both aerobic and anaerobic), gram-negative enteric bacilli, and anaerobes (*B. fragilis*),

interacting synergistically, have been implicated in this infection (1). The onset can be acute or subacute, but the infection rapidly progresses to severe local and systemic toxicity with high fever. There is often severe pain at the site of infection, and the skin is blue-gray. Necrosis of the fascia and muscle occurs. Twenty-five percent of cases have clinical crepitance and gas evident on radiographs. The exudate is thin and foul-smelling and has the appearance of dish water. Bacteremia occurs in 50% of cases and mortality has been reported to be as high as 75% (12).

Necrotizing fasciitis is predominantly a disease of the subcutaneous tissue and fascia, with early sparing of the skin and very late involvement of the muscle. This condition can occur after trauma or abdominal surgery or with perirectal infections, cutaneous ulcers, IV drug abuse, and infections of the head and neck. A wide range of organisms, including gram-negative enteric bacilli, gram-positive streptococci (aerobic and anaerobic), and other anaerobes, has been implicated. Although the infection is usually mixed, it can also be caused by single organisms, such as group A *Streptococcus* (23). The onset is acute and the patient develops severe systemic toxicity. In the early stages, the skin appears erythematous and is minimally painful. Later, as the subcutaneous tissue becomes involved, there is mottling, discoloration, marked edema, and bleb formation as a result of interruption of the blood supply to the skin. The exudate is foul-smelling and seropurulent but not abundant. Although gas can be seen on radiographs, clinical crepitance is unusual.

Clostridial cellulitis, also known as *clostridial anaerobic cellulitis,* is most commonly a result of traumatic wounds. The presence of foreign debris, soil, and necrotic tissue allows rapid growth of clostridial organisms, including *Clostridium perfringens, Clostridium septicum,* and *Clostridium novyi.* It is distinguished from clostridial myonecrosis (gas gangrene) by the lack of muscle involvement. Unlike gas gangrene, the onset is gradual, and systemic toxicity is only mild to moderate. Skin changes are minimal, but there is a thin, dark, occasionally foul-smelling exudate at the site of the wound. The most prominent features of the wound site are crepitance and gas formation that often extend well beyond the actual area of

cellulitis. The gas tends to appear on a radiograph as aggregates of bubbles in the subcutaneous tissues.

Clostridial myonecrosis, or gas gangrene, almost always results from a deep injury to skeletal muscle that causes ischemia and tissue necrosis. The same organisms that cause clostridial cellulitis are responsible for this disorder. The incubation period can range from 7 hours to 6 weeks, but once symptoms begin, severe deterioration can occur within 6 hours. Muscle swelling and severe pain are prominent features. Systemic toxicity, as a result of the many toxins elaborated by the clostridial organisms, is profound and leads to tachycardia and an altered sensorium, although fever is not a prominent feature. The involved skin has a yellow or bronze appearance, and the skin involvement progresses to bulla formation and green or black patches of necrosis. A serosanguineous discharge can develop with a characteristic "mousy" odor. Gas formation is minimal at the onset but extends throughout the muscle in a feathery pattern as it dissects through muscle fibers and bundles. Intravascular hemolysis, with thrombocytopenia, is often present. *Affected patients can die within hours.*

DIFFERENTIAL DIAGNOSIS

There is little difficulty in recognizing the picture of full-blown deep cutaneous and necrotizing soft tissue infections. Occasionally, they can be confused with such conditions as dry ischemic vascular gangrene, pressure necrosis of a limb, acute deep venous thrombosis, and pre-existing changes of venous insufficiency. Air can be introduced into the skin by traumatic lacerations and occasionally can cause some diagnostic concern.

It is important to emphasize, however, that these infections can be missed when they are not full blown. This is where difficulty can arise for the patient presenting to the ED in the early stages of infection.

ED EVALUATION

The presence of a suspected deep cutaneous infection mandates an extensive and aggressive evaluation with early surgical consultation.

This must be initiated promptly and carried out while any resuscitative or stabilizing interventions are in progress. Standard hematologic, biochemical, and clotting profiles are obtained as are arterial blood gas studies, a chest radiograph, and an electrocardiogram. A type and crossmatch may be indicated to correct blood loss or anemia. Imaging of the affected area with x-ray, CT, MRI, and/or ultrasound can be helpful in heightening suspicion for a deep space infection; however, it does not rule in or out the diagnosis. Obtaining imaging should not delay surgical consultation or definitive treatment.

A wound culture is taken and a gram stain performed immediately, particularly if a clostridial etiology is suspected. The presence on gram stain of gram-positive rods with few white blood cells indicates a clostridial infection. A finding of many white blood cells on the smear is more suggestive of a synergistic or mixed bacterial infection. Radiographs of anatomic areas of concern are obtained to look for soft tissue gas. Because the infection can advance up to 10 cm an hour, the area of involvement should be outlined with a marker and checked at frequent intervals.

KEY TESTING

- Laboratories
  - CBC
  - Blood glucose, electrolytes, BUN, Cr
  - Blood cultures, wound cultures
  - Lactate
  - CK
  - CRP
  - PT/ PTT/INR
- Imaging
  - X-ray, CT, MRI to assess for the presence of gas in tissue
  - Ultrasound to assess for the presence of fluid tracking along facial planes

ED MANAGEMENT AND DISPOSITION

Because it can progress so rapidly, clostridial myonecrosis is a true emergency. Concurrent with ED evaluation, planning and execution of intervention is carried out in consultation with a surgeon. A combination of hyperbaric oxygen (HBO), surgery, and antibiotics provides optimal treatment (24). HBO can arrest the advance of the hemolytic, necrotizing, and potentially lethal tissue toxins. HBO produces a tissue level of 300 mm Hg, which is 50 mm Hg in excess of that required to cause bacteriostasis and halt production of tissue toxins. HBO significantly reduces the need for extensive debridement and amputation and assists the surgeon in demarcating clearly necrotic from viable tissue. If necessary, however, a fasciotomy can be performed before HBO is done to relieve compartmental swelling and pressure.

In clear cases of clostridial myonecrosis or cellulitis, high-dose penicillin is still the antibiotic of first choice. Clindamycin can be used in β-lactam–sensitive patients. If the diagnosis is uncertain, the antibiotics listed in Table 180.2 are also appropriate choices. Antitoxin therapy has never proven efficacious.

The primary treatment for other deep cutaneous infections consists of antibiotics and surgical intervention (21). Patients with an immunocompromised state or rapidly spreading infection can benefit significantly from adjunctive HBO; this intervention should be considered for all patients with these infections, especially Fournier gangrene (24). Broad-spectrum antibiotics are usually initiated empirically in the ED (Table 180.2).

CRITICAL INTERVENTIONS

- When draining an abscess, be sure the incision extends across at least two-thirds the diameter of the actual cavity to allow for gentle probing and disruption of loculations.
- Initiate therapy for *N. gonorrhoeae* and *Chlamydia trachomatis* when treating Bartholin abscesses.
- Treat *clostridial myonecrosis* with a combination of HBO, surgery, and antibiotics.

Common Pitfalls

- Failing to recognize a deep cutaneous infection because of a lack of the classic skin changes of cellulitis
- Failing to perform a Gram stain in the ED
- Failing to take radiographs and thus missing subcutaneous gas
- Initiating only limited-spectrum antibiotics
- Delaying surgical consultation

CHAPTER 181

Tetanus

Daniel T. Wu

Tetanus ("lockjaw") is a severe and often fatal disease caused by the gram-positive anaerobic organism *Clostridium tetani.* The infection has been described in the medical literature as far back as the 5th century BC, and the organism can be found almost ubiquitously in nature, especially in soil and feces (1). The success of an aggressive vaccination program started in the 1940s, combined with improved sterilization procedures, has made tetanus a rare disease in the United States. There were an average of 31 cases per year in the United States from 2000 to 2007, dropping to an all-time low of 18 cases in 2009 (1). Despite the availability of an effective vaccine, tetanus still remains prevalent in many Third World countries with an estimated incidence of 500,000 to 1 million cases per year and a mortality rate as high as 20% to 30% (2–4).

The *C. tetani* bacterium is heat sensitive and cannot survive in the presence of oxygen, but it produces spores that are heat resistant and can survive indefinitely until they germinate. This germination can occur weeks after entry into a wound and accounts for many of the infections that occur after a wound has fully healed. Under anaerobic conditions, the spores germinate into mature organisms and release two neurotoxins, tetanolysin and tetanospasmin. Tetanolysin is known to cause tissue damage but is not thought to be a major contributor to the clinical manifestations of tetanus. Tetanospasmin is a very potent neurotoxin, which enters peripheral nerves and travels retrograde to the central nervous system (CNS) where it disrupts the release of inhibitory neurotransmitters such as γ-aminobutyric acid (GABA). This disruption leads to uncontrolled

motor nerve activity and the clinical manifestations of muscle spasms and autonomic instability that characterize tetanus infections. The incubation period is approximately 1 week but can be as short as 2 to 3 days or as long as several weeks (1,5,6). A shorter incubation period is generally associated with more severe disease and an increased risk of death.

CLINICAL PRESENTATION

There are four different types of tetanus infections: generalized, localized, neonatal, and cephalic.

Generalized tetanus is the most common type and represents approximately 80% of all tetanus infections in the United States and developed countries. Symptoms usually start with muscle stiffness and pain, most often occurring in the facial and jaw muscles causing trismus, and frequently resulting in the characteristic facial appearance known as *risus sardonicus*. The symptoms spread to the neck, torso, and extremities. Tetanic spasms of the back muscles produce opisthotonos, where only the back of the head and the heels rest on the bed. Spasms may involve the muscles of respiration, producing a fixed chest wall and eventual asphyxia.

Systemic symptoms in mild cases are often minimal, but in severe cases marked autonomic disturbances are seen with tachycardia, wide swings in blood pressure, hyperpyrexia, and cardiac dysrhythmias. These manifestations appear to be due to excessive catecholamine release and are the most common cause of death from tetanus. Trivial stimuli may trigger not only severe spasms but also wide swings in vital signs.

Localized tetanus is a less common form of the disease and accounted for 17% of cases in the United States from 1998 to 2000 (5). This form of the disease manifests as localized spasms around the area of initial infection and may last for weeks before fully resolving. The prognosis of localized infections is very good with a mortality rate of approximately 1% (2,5). It is important to note that what may appear to be a localized infection could be the early stages of a generalized infection.

Neonatal tetanus is a generalized form of tetanus that occurs in neonates during the first few weeks of life and is often caused by infection of the umbilical stump. The initial symptoms are spasms, rigidity, and poor feeding. Neonatal tetanus has become a rare disease in the United States since the introduction of the tetanus vaccine and modern sterilization techniques. It remains a serious problem in many developing countries where babies are born without passive immunity because their mothers have not been vaccinated. Worldwide, the neonatal form of tetanus accounts for more than half of all tetanus deaths (7).

Cephalic tetanus is a very rare variant of the disease that often occurs after head injury or otitis media. Trismus and cranial nerve involvement are characteristic. The seventh and sixth cranial nerves are most commonly involved. Cephalic tetanus can initially be misdiagnosed as Bell palsy.

DIFFERENTIAL DIAGNOSIS

The only entity that an established case of tetanus may be confused with is strychnine poisoning. Muscle spasms associated with strychnine poisoning may resemble those of tetanus, but there are several important differences. The muscles of the jaw are not involved early in the course of strychnine poisoning or may be spared completely. In tetanus, the jaw muscles are involved early in the course, and trismus is almost always present. In a patient with strychnine poisoning, muscle rigidity disappears completely between spasms.

The early stages of tetanus may be confused with psychoneurotic complaints and with dystonic reactions from such agents as phenothiazines. Dystonic reactions can be rapidly and safely treated and ruled out by the administration of benztropine or diphenhydramine. Dental infections may produce trismus, but there is no progression, and signs of local infection are almost always present.

ED EVALUATION

The diagnosis of tetanus remains a clinical one, and laboratory testing offers little or no benefit. Wound cultures and serum antitoxin antibody levels can be obtained, but neither is available quickly enough to make the diagnosis during the initial presentation of the disease (8). Wound cultures for tetanus are positive only about 30% of the time. Laboratory studies, although not diagnostic for tetanus infections, should be sent to rule out other etiologies and to assess oxygenation status in severe infections.

The source of the infection should be investigated. Wounds secondary to acute trauma account for the majority of cases in the United States, but an acute skin wound is not necessary to contract a tetanus infection, and the incubation period can be quite long. Of the confirmed tetanus cases from 2001 to 2008, only 72% reported a wound from acute trauma, with almost 10% of cases reporting no wounds or infections (1).

The majority of cases in the United States have occurred in patients who were inadequately vaccinated or who had an unknown vaccination history. Several groups appear to be at risk for developing tetanus. These groups include the elderly, diabetics, and injection-drug users (IDUs) (1,5,9). The elderly are at a greater risk because of declining immunity over time (9,10). Protection, as defined by adequate serum antibody levels, decreases with age, and it was found that only $>30\%$ of people older than 70 years of age had protective levels of antibodies (9).

ED MANAGEMENT

The management of tetanus has three goals: stabilizing the patient, neutralizing the toxin, and removing any remaining organisms.

In the initial stages, management is largely supportive with emphasis on airway control. Patients with severe infections may require ventilatory support to prevent asphyxiation from severe muscle spasms. Airway management may be difficult because of trismus and may require the use of paralytic agents. Succinylcholine can be used in early tetanus but should be used with caution, if at all, in the later stages of the disease because of the risk of

hyperkalemia secondary to the up-regulation of acetylcholine receptors. Prophylactic intubation should be considered in the early stages of cases in which the airway may be threatened. Severe muscle spasms and rigidity can be treated with benzodiazepines but often require large doses.

The toxin should be neutralized by the administration of tetanus immune globulin (TIG). The dose is 3,000 to 6,000 units intramuscularly (IM) for both adults and children (1,11). Some authorities have recommended part of the dose be locally infiltrated around the wound, although this practice may cause local irritation and has not been proven to be beneficial. TIG does not affect toxin already bound to nerve endings, but it can help to remove unbound toxin.

Removal of any remaining tetanus organism is important in limiting the severity of infection. If a wound is identified, it should be cleaned well and debrided to remove any necrotic tissue. Metronidazole is effective in eliminating *C. tetani* and has become the antibiotic of choice, with penicillin as an alternative treatment (11,12).

Autonomic instability, which manifests as hypertension and tachycardia, usually occurs days to weeks after the onset of symptoms and is also a major cause of death. Fatality rates are as high as 28% (2). There is no universally accepted treatment protocol, but labetalol has been used frequently for its β- and α-blocking effects. Other agents that have been used with varying effectiveness include opiates, clonidine, and magnesium.

Clinical infection does not confer immunity, so all patients who recover from tetanus must be actively immunized.

CRITICAL INTERVENTIONS

- Administer tetanus toxoid and TIG for tetanus-prone wounds, if a patient has not previously completed a full vaccination series.
- Administer tetanus toxoid if the patient has not received tetanus toxoid within 5 years for tetanus-prone wounds or within 10 years for nontetanus-prone wounds.

DISPOSITION

All patients with clinical tetanus must be admitted to an intensive care setting for observation and management. Because it is difficult to predict the severity and progression of the disease when it is in its early stages, patients should be monitored to ensure maintenance of an airway and to identify and treat autonomic instability and cardiac arrhythmia.

PREVENTION

With the introduction of an effective vaccine in the 1940s and improved sterilization techniques, tetanus has become an almost entirely preventable disease. There has been a steady decline in both the incidence of the disease and mortality rates. Because almost all recent cases of tetanus in the United States have occurred in persons who have never been vaccinated or have not had a recent booster, it is the responsibility of emergency physicians to inquire about the immunization status of all patients and administer the toxoid and/or immune globulin as indicated.

For clean, minor wounds, tetanus toxoid is indicated if the patient has received fewer than three doses of the vaccine in the past, if the vaccination history is unknown, or if it has been more than 10 years since the last Td booster. For tetanus-prone wounds (those contaminated with feces, dirt, or saliva, as well as burns, crush injuries, and puncture wounds), tetanus toxoid should be administered if the patient has not received it within the last 5 years. TIG should also be administered if the patient has not previously completed a full vaccination series (Table 181.1).

TABLE 181.1
Tetanus Prophylaxis for Wound Management

Vaccination history (prior Td doses)	*Clean, Minor Wounds*		*All Other Wounds*	
	Tetanus toxoid	TIG	Tetanus toxoid	TIG
Unknown or <3 doses	Yes	No	Yes	Yes
3 or more doses	No[a]	No	No[b]	No

[a]Tetanus toxoid should be given if more than 10 yrs since last booster.
[b]Tetanus toxoid should be given if more than 5 yrs since last booster.
Note: Tetanus Toxoid can be given as Td, Tdap, DT, or DTaP.
From Center for Disease Control. *Epidemiology and Prevention of Vaccine-Preventable Diseases* (The Pink Book), 10th ed., and Pickering L, ed. *2006 Red Book: Report of the Committee on Infectious Diseases*, 27th ed. American Academy of Pediatrics; 2000.
TIG, tetanus immune globulin.

The primary vaccination series should be completed by the age of 18 months. Children should receive a booster at ages 4, 11, and every 10 years thereafter.

The tetanus toxoid is available combined with the diphtheria toxoid (DT, Td) or combined with the pertussis vaccine (DTaP, Tdap). The recommended preparation is dependent on the patient's age and prior immunization status. Children younger than 7 years of age should receive the pediatric formulations (DT, DTaP) unless contraindicated. In 2005, Advisory Committee on Immunization Practices (ACIP) recommended that Tdap be given to all patients aged 11 to 64 years for booster immunization instead of Td (if they have not previously received a dose of Tdap). If Tdap is not available, Td can still be used (13). In children between 7 and 10 years of age, both Td and Tdap (if under immunized for pertussis) can be used (11). Updated recommendations in 2010 have extended the use of one dose of Tdap to patients aged 65 years or older, if they have close contact to an infant 12 months of age, or have not previously received Tdap.

Common Pitfalls

- Clinical tetanus infection does not confer immunity, and active immunization should be given to all patients who have infections.
- The elderly are at particular risk for contracting infections because of their declining immunity.

- An acute laceration is not required to develop tetanus. Infections can originate from lacerations that have already started healing or from other sources such as abscesses, ulcers, or injection sites in drug users.

CHAPTER 182

Meningitis and Encephalitis

Richard M. Kaplan

The annual incidence of bacterial meningitis ranges from 1.3 to 6 cases per 100,000 adults in the United States (US) to 500 cases per 100,000 in the "meningitis belt" of Africa. Recent publications report 4,100 cases of bacterial meningitis a year in the US with a median age of 41 and an overall mortality of 15%. The major causes of bacterial meningitis are *Streptococcus pneumoniae* (58%), group B streptococcus (GBS) (18.1%), *Neisseria meningitidis* (13.9%), *Haemophilus influenzae* (6.7%), and *Listeria monocytogenes* (3.4%) (1–8).

Bacterial meningitis has decreased markedly due to the vaccines for *H. influenzae* type B (Hib), *S. pneumoniae,* and *N. meningitidis.* The vaccines are listed in **Tables 182.1** and **182.2**. The meningococcal vaccines have been recommended for children with terminal complement deficiencies, functional or anatomic asplenia, and other high-risk groups. The quadrivalent meningococcal vaccine (A, C, Y, W-135) is recommended for outbreaks and military personnel.

TABLE 182.1
Pneumococcal and H. influenzae Vaccines

Age	Vaccine
2, 4, 6, 12–15 mos	Pneumococcal conjugate and *H. influenzae* serotype B
>2 yrs	Pneumococcal polysaccharide

TABLE 182.2
Meningococcal Vaccines

Age	Vaccine
6 wks–18 mos	MenHibrix (Hib, MenCY-TT) (conjugate)
9–23 mos	MenACWY-D (conjugate)
2–55 yrs	MenACWY-D, MenACWY-CRM (conjugate)
11–12 yrs	MenACWY with booster at 16 yrs of age (conjugate)
>=56 yrs	MPSV4 (polysaccharide)

For children under the age of 2 months, GBS accounted for 86% of cases of bacterial meningitis. GBS screening during pregnancy has decreased the incidence of these infections. *L. monocytogenes* is generally found in children younger than 3 months, but it is also an important cause of meningitis in elderly and immunocompromised patients.

Nosocomial meningitis may result from invasive neurosurgical procedures (craniotomy, ventricular catheters, lumbar puncture (LP), intrathecal infusions, spinal anesthesia), head trauma, bacteremia, or immunocompromised conditions (3,9,10). Staphylococcal species and gram-negative bacilli are more commonly found in nosocomial meningitis. *S. pneumoniae* has been identified following basilar skull fractures or ENT surgeries. Coagulase-negative staphylococci or *Propionibacterium* acnes have been identified in patients with ventricular drains.

The incidence of meningitis following moderate or severe head trauma has been estimated at 1.4%. The rate of meningitis may increase to 2% to 11% following open compound cranial fractures. Following basilar skull fractures, the median onset for meningitis is 11 days, and infection rates may reach 25% (10).

Fungal meningitis should be suspected in immunocompromised patients. Fungal meningitis was recently reported following epidural

injections with contaminated methylprednisolone products. An index case was reported for *Aspergillus fumigatus* (11), while a follow-up study documented fungal meningitis due to *Exserohilum rostratum* (12).

Risk Factors

Risk factors associated with bacterial meningitis include age (the very old and the very young), ear-nose-throat conditions (otitis, mastoiditis, sinusitis), neurosurgical procedures, chronic disease, diabetes mellitus, immunosuppression, HIV, men who have sex with men (MSM), alcohol abuse, and tobacco exposure. Overcrowded living conditions (e.g., college dormitories, military barracks) and poverty increase the risk of contracting meningococcal meningitis (13,14). Risk factors for *Listeria* meningitis include an immunocompromised status and the ingestion of *Listeria*-contaminated foods such as uncooked meats, vegetables, soft cheeses, cold cuts, and unpasteurized milk.

Aseptic Meningitis

Aseptic meningitis is primarily of viral etiology and is generally a self-limited symptom complex of fever, headache, and nuchal rigidity with cerebrospinal fluid (CSF) findings of lymphocytosis, variable protein elevation, and normal glucose. Enterovirus is the most common cause of aseptic meningitis (15).

Encephalitis

Acute encephalitis is a viral-related illness in which the brain is injured either as a direct result of viral invasion or as a hypersensitivity reaction to a systemic viral illness. Encephalitis may occur shortly after vaccination for measles, rubella, chickenpox, or rabies. The diagnosis of encephalitis should be considered in patients who present with fever, headache, nuchal rigidity, altered mental status, seizures, or focal neurologic signs. In the United States, the most common causes of acute encephalitis include herpes

simplex virus (HSV), enteroviruses, arboviruses, and HIV. The arboviruses include West Nile virus (WNV), St. Louis, California, Western, and Eastern equine. In 2002, a WNV outbreak of arboviral meningoencephalitis resulted in a 9% mortality (16), whereas mortality due to HSV encephalitis ranges from 30% to 60% (17).

CLINICAL PRESENTATION

Fever, headache, altered mental status, and nuchal rigidity should prompt serious consideration of the diagnosis of meningitis. Fever was reported in 85% to 97%, neck stiffness in 70% to 88%, and altered mental status in 66% to 78%. The triad of these findings has been documented in 21% to 67% of patients with meningitis (3,6,7,9). Infections from CSF shunts may cause only low-grade fever or malaise; meningeal irritation may be seen in less than 50% of these patients.

Several clinical signs should be assessed in the physical examination, but they are not pathognomonic of meningeal irritation. Nuchal rigidity is characterized by neck stiffness and the inability to passively flex and extend the head in a normal manner. The Brudzinski sign occurs when flexion of the neck results in flexion of the knees and hips. The Kernig sign is elicited by extending the knee with the hip flexed; stretching of the lumbar roots causes pain in the hamstring and paraspinal muscles. A prospective study (18) of 297 patients with suspected meningitis observed that neither Kernig sign, Brudzinski sign, nor nuchal rigidity accurately diagnosed meningitis. For nuchal rigidity, the sensitivity was 30% whereas the sensitivities for Kernig and Brudzinski signs were 5%. The jolt accentuation test, horizontal movement of the head at a frequency of 2 to 3 rotations/sec, has also been recommended to assess for the possibility of meningitis. A positive test is a worsening of the baseline headache.

Most patients with meningitis do not present with a rash. Durand (3) reported a rash in 11% (30 of 279), whereas Van de Beek et al. (6,7) reported a rash in 26% (176 of 683), of which *N. meningitidis* was the bacteria in 162 episodes. Petechiae, purpura, and

morbilliform rash are commonly noted in association with meningococcal meningitis (19). In one study, 80% of the patients with *N. meningitidis* had a purpuric or petechial rash, whereas similar findings were noted in 7% of patients with *S. pneumoniae.* Rashes may also be seen with *Staphylococcus, H. influenzae,* or viral meningitis.

Mental status or behavioral changes are commonly noted with encephalitis. Any of the encephalitides may demonstrate hypersomnia as an acute symptom. Following a WNV outbreak in New York City, neurologic abnormalities included abnormal cranial nerve function (22%), diffuse flaccid paralysis (10%), and seizures (3%) (16).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of meningitis and encephalitis includes infectious, neurologic, toxicologic, metabolic, environmental, and behavioral disorders. Migraine and seizures may present with symptoms common to both encephalitis and meningitis. Behavioral alterations (e.g., psychosis, mania) should never be considered to be purely of psychological origin without an evaluation for the possibility of underlying organic causes such as meningitis and encephalitis.

ED EVALUATION

The majority of patients with meningitis or encephalitis who present to the emergency department (ED) display the classic complaints of severe headache and fever. Patients may not present with the "classic" findings, and one must have a low threshold for performing an LP. Increased surveillance is warranted in HIV patients. If meningitis is suspected, appropriate laboratory studies and cultures are drawn, and antibiotics are promptly administered.

Identification of risk factors may aid in the early diagnosis of meningitis. Most risk factors can be identified with a few questions guided by the six I's as follows:

- Infection (upper or lower respiratory tract infection, sinusitis, otitis)
- Immunosuppression (splenectomy, sickle cell disease, corticosteroids, Hodgkin disease, myeloma, organ transplant, HIV)
- Injury (head trauma, neurologic or ENT procedures)
- Indwelling (catheters, shunts, ventricular reservoirs)
- Imbiber (alcoholic)
- Identification (close contacts)

Many of the more common viruses causing outbreaks of encephalitis demonstrate characteristic seasonal and geographic distributions. Arbovirus and enterovirus infections tend to occur in summer and early fall. Eastern equine encephalitis occurs in the eastern United States, and Venezuelan equine encephalitis is generally found in Florida and the southwestern United States, whereas herpes simplex encephalitis demonstrates no characteristic geographic pattern. WNV has spread from the East coast to the Pacific coast with about 85% of human infections occurring in August and September (16). Some important data to be elicited in suspected cases of encephalitis can be summarized through the use of the six V's as follows:

- Vacation/travel (to endemic areas, foreign, or domestic)
- Veterinary or other animal contact (rabies)
- Vectors (recent mosquito or tick bites)
- Viral infections (recent or concurrent)
- Vaccinations (recent for measles, varicella, rubella, rabies)
- Vital statistics (contact health agencies regarding outbreaks)

The physical examination should focus on possible sources of infection including the oropharynx, ears, sinuses, chest, abdomen, and skin. The entire body should be scrutinized for the presence of any rashes.

Computed Tomography Scan

If a patient has a suspected cerebral mass, focal neurologic findings, a prolonged or deteriorating course, or papilledema, a computed tomography (CT) of the head should be performed. Hasbun et al.

(20) reported that an age of 60 years or older, immunocompromised status, history of CNS disease, seizure within the last week, abnormal language, inability to correctly answer two consecutive questions, and abnormal level of consciousness were among the findings associated with an abnormal head CT. The CT scan should be assessed for the presence of a space-occupying lesion, edema, or evidence of brain shift (4).

Lumbar Puncture

Lumbar puncture is the key to confirming the diagnosis of meningitis and encephalitis. Contraindications to LP include infection at the site of the puncture and evidence of obstructive (noncommunicating) hydrocephalus. CSF evaluation includes a cell count and differential, Gram stain, culture, protein, and glucose. CSF tests may also include bacterial antigens, polymerase chain reaction (PCR), lactate, or antibody titers.

Cerebrospinal Fluid Parameters

Gram Stain, India Ink, Acid-Fast

Gram stains of CSF have sensitivities ranging from 50% to 90% (3,6,7). A negative Gram stain does not rule out the possibility of bacterial meningitis. If the Gram stain is negative and one has a high suspicion for meningitis, the patient should be treated with appropriate antibiotics and admitted to the hospital.

There are limited studies evaluating the effects of antibiotics on CSF parameters. It is unlikely that antibiotic administration will alter CSF parameters within 1 to 2 hours (21,22). A retrospective pediatric bacterial meningitis study noted that 44 to 68 hours of antibiotics did not alter the CSF cytology and biochemistry in 65 of 68 children (23).

India ink preparations for the detection of fungal elements in CSF are positive in as few as one-half of cases. Acid-fast smears of CSF for diagnosing tuberculous meningitis are not consistently sensitive.

Antigen, Polymerase Chain Reaction, and Antibody Detection

CSF antigen studies are available for *H. influenzae* type B, *N. meningitidis* A, B, C, Y, W-135, *Streptococcus agalactiae* (group B), *S. pneumoniae,* and *Escherichia coli.* These antigen studies may identify an organism when the Gram stain is equivocal or "negative." After antibiotic therapy, bacterial antigens may persist in the CSF for several days (22).

PCR tests may identify serogroup-specific *N. meningitidis* DNA (14), enterovirus (15), or specific viruses (24). One study used PCR to detect gram-positive bacteria in 86 specimens; 42 were positive with PCR and had negative cultures. There were no positive culture results in patients with a negative PCR (10,25). Antibody detection may also be used for detecting CNS infections. IgM antibodies in the CSF may be detected within 8 days of symptoms in patients with WNV meningoencephalitis (16).

Glucose

The normal ratio of CSF to serum glucose concentration is 0.6. A CSF glucose level of <50 mg/dL or a CSF/serum glucose ratio of <0.5 is noted in more than 50% of cases of bacterial, fungal, and tuberculous meningitis. Normal CSF glucose levels are generally noted in most viral meningitides and encephalitides.

Protein

Normal protein levels in the CSF range from 15 to 45 mg/dL. Subarachnoid space infection results in increased protein permeability of the choroid plexus, ependyma, and pia mater. Marked protein elevations are observed in bacterial, fungal, and tuberculous meningitis. Normal or moderately elevated levels of protein are found in viral meningitides or encephalitides (26). The CSF protein level has been reported to increase 1 mg/dL for every 1,000 red blood cells (RBCs) in the CSF.

Lactic Acid

CSF lactic acid levels are usually normal in viral meningitis and have been reported to be elevated in bacterial, fungal, and tuberculous meningitis (26).

Cell Count and Differential

CSF findings in bacterial meningitis, aseptic meningitis, and encephalitis may not clearly establish a diagnosis. Normal CSF has a white blood cell (WBC) count of <5 cells/mm^3 with only mononuclear cells. After centrifugation, the finding of a single CSF granulocytic cell may be considered normal if the total CSF WBC count is <5 cells/mm.

For bacterial meningitis, CSF cell counts usually range from 100 to 10,000 cells/mm^3 with predominately polymorphonuclear white cells. As many as 10% of patients with bacterial meningitis initially demonstrate a CSF lymphocytosis (27). Not all the parameters are necessarily abnormal with bacterial meningitis. WBC count <100 cells/mm^3, negative Gram stain, or normal CSF glucose and protein levels (6,7,9) may be present in patients with bacterial meningitis.

CSF lymphocytosis with cell counts of 10 to 1,000 cells/mm^3 is usually seen with viral meningitis. In viral meningitis, there is usually a predominance of mononuclear cells, a normal glucose concentration, and a slightly-to-moderately increased protein level. Occasionally, in early cases of viral meningitis, the CSF WBC count will exceed 1,000 cells/mm^3 and the neutrophils will predominate.

In the acute stages of viral encephalitis, a mild-to-moderate rise in mononuclear lymphocytes (e.g., 10 to 250 cells) is noted, with higher cell counts suggestive of concomitant meningeal involvement. In WNV meningoencephalitis, CSF findings include an elevated protein count and pleocytosis with a predominance of lymphocytes.

Mononuclear cells usually predominate in cases of tuberculous, fungal, or aseptic meningitis. Tuberculous and fungal meningitis may also present with CSF findings of neutrophilia, a normal-to-decreased glucose, and an elevated protein.

A traumatic LP may lead to an increase of one WBC for 700 to 1,000 RBCs. The hemorrhagic lesion of herpes encephalitis may lead to an elevated RBC count in the CSF or xanthochromia.

Cultures

The CSF should be cultured in all cases of suspected meningitis. A negative CSF culture has been reported in 11% to 30% of patients

with bacterial meningitis (3,6). The diagnosis of meningitis is made only from the culture in about 20% of cases (28). A retrospective pediatric meningitis study (29) of 16 treated patients with meningococcal or pneumococcal meningitis documented sterile CSF for all nine meningococcal CSF cultures (2 hours), and sterile CSF for only one of seven *S. pneumoniae* cultures (4.3 hours). Overall, negative CSF cultures were seen in 8% of patients who were not pretreated with antibiotics and in 44% who had been pretreated with antibiotics. Sigurdardottir et al. (30) reported negative blood and CSF cultures in 11% of patients with meningitis. Talan et al. (22) noted that only about 50% of patients with bacterial meningitis had positive blood cultures.

ED MANAGEMENT

The patient who presents to the ED with fever, nuchal rigidity, altered mental status, and headache should be considered to have meningitis until proven otherwise. One should also look for atypical presentations of meningitis and be aware that patients may present with only one or two of the findings of the meningitis triad. If meningitis is suspected, antibiotic therapy should be promptly administered. Empiric antibiotic therapy for bacterial meningitis should treat *S. pneumoniae, N. meningitidis,* and *H. influenzae* (Table 182.3). Patients should be promptly treated with a third-generation cephalosporin (cefotaxime or ceftriaxone) and vancomycin (21). Dexamethasone (10 mg) has been suggested to improve outcomes, particularly in patients with penicillin-susceptible pneumococcal meningitis (31).

TABLE 182.3
Empiric Parenteral Antibiotic Therapy for Meningitis in Adults

Ceftriaxone (2 g IV q12h) or cefotaxime (2 g IV q4–6h) and vancomycin (15 mg/kg q8–12h)

If penicillin/cephalosporin allergy and unable to administer third-generation cephalosporin, consider ID consult. Options may include:

Vancomycin (15 mg/kg IV q8–12h) and chloramphenicol (25 mg/kg; max 1 g q6h) or vancomycin (15 mg/kg IV q8–12h) with[a] ciprofloxacin (400 mg IV q8–12h) or other appropriate quinolone

Dexamethasone 10 mg (IV q6h) for suspected pneumococcal meningitis

If suspicion of listeria (adults >50 yrs old):

Ampicillin (2 g IV q4h) or

Trimethoprim/sulfamethoxazole (15–20 mg/kg/d based on trimethoprim component, divided q6h)

[b]Gentamicin (5 mg/kg/d divided q8h); other aminoglycosides have also been recommended

If suspicion of group B streptococcus:

Ampicillin (2 g IV q4h)

Nosocomial Meningitis

Postneurosurgical infection, ventricular or lumbar catheter, penetrating trauma:

Vancomycin (15 mg/kg IV q8–12h) and

cefepime (2 g IV q8h), ceftazidime (2 g IV q8h), or meropenem (2 g IV q8h)

Basilar skull fracture

Vancomycin (15 mg/kg IV q8–12h) and

ceftriaxone (2 g IV q12h) or cefotaxime (2 g IV q4–6h)

If severe allergy to penicillin or cephalosporins:

Aztreonam (2 g IV q8h) or ciprofloxacin (400 mg IV q8–12h) for gram-negative bacilli

If resistant gram-negative rods, such as pseudomonas:

Consider the addition of ceftazidime (2 g IV q8h) and

gentamicin (5 mg/kg/day divided q8h)

If brain abscess:

Ceftriaxone (2 g IV q12h) and metronidazole (500 mg IV q8h)

or

Vancomycin (15 mg/kg IV q8–12h) and cefepime (2 g IV q8h)

If suspicion of cryptococcal infection in the HIV patient, options may include:

Amphotericin B deoxycholate (0.7–1 mg/kg/d) and flucytosine (100 mg/kg/d divided q6h)

Other medications used have included:

Lipid formulations of amphotericin B:

Lipid complex: 5 mg/kg IV q24h

Liposomal: 3–4 mg/kg IV q24h

[a]Quinolones are not promoted for use in bacterial meningitis.

[b]Other aminoglycosides may include tobramycin (5 mg/kg/d divided q8h) or amikacin (15 mg/kg/d divided q8–12h).

There are limited options available to the emergency medicine physician when a third-generation cephalosporin cannot be administered. Chloramphenicol has been recommended, but it may not be available on the hospital formulary. Vancomycin does not by itself provide ideal coverage for empiric treatment of bacterial meningitis. Quinolones have been used for treating bacterial meningitis in patients with a documented penicillin or cephalosporin allergy (32,33).

Highly lipid-soluble antibiotics such as chloramphenicol, rifampin, and trimethoprim achieve high penetration into the CSF (21). Rifampin has a synergistic action with ceftriaxone against β-lactam–resistant *S. pneumoniae* (10,21). Trimethoprim/sulfamethoxazole may be used to treat *L. monocytogenes* if there is an ampicillin allergy. Aminoglycosides have been used for treating CNS infections, but they have poor CNS penetration (32). Ceftazidime (Fortaz) has been recommended for treating bacterial meningitis due to gram-negative rods.

For HIV-associated cryptococcal meningoencephalitis, intravenous amphotericin B deoxycholate and flucytosine are recommended as primary induction and consolidation therapy. If there is concern for nephrotoxicity, lipid formulations of amphotericin B may be considered.

For herpes encephalitis, intravenous acyclovir (10 mg/kg) is administered over 1 hour. The identification of nonviral agents of encephalitis (e.g., syphilis, toxoplasmosis, tuberculosis) will guide specific therapy.

For patients with suspected viral meningitis who are admitted to hospital, the decision to institute antibiotic coverage in the ED should be made by the emergency medicine physician on the basis of the patient's clinical picture and associated risk factors.

Chemoprophylaxis

Chemoprophylaxis regimens for meningococcal disease are listed in Table 182.4. Close contacts (e.g., families, roommates, daycare

contacts) of patients with meningococcal meningitis have an increased risk (400- to 800-fold) of contracting the disease (14). Prehospital and hospital personnel along with other close contacts of patients with meningococcal or *H. influenzae* meningitis should receive chemoprophylaxis. Five percent to 10% of adults are asymptomatic nasopharyngeal carriers of *N. meningitidis,* and most are not pathogenic. There is no indication to treat individuals who are asymptomatic nasopharyngeal carriers. Oropharyngeal or nasopharyngeal cultures are not helpful in determining the need for chemoprophylaxis (14).

TABLE 182.4
Chemoprophylaxis for Meningococcal Disease

Drug	Age	Dosage	Duration and Route[a]
Rifampin	>=1 mo	10 mg/kg BID	2 d oral
Rifampin	Adults	600 mg BID	2 d oral
Ciprofloxacin	Adults	500 mg	Single dose oral
Ceftriaxone	<15 yrs	125 mg	Single IM dose
Ceftriaxone	Adults	250 mg	Single IM dose
Azithromycin	Adults	500 mg	Single oral dose

[a]IM, intramuscular.

Antibiotics that eliminate nasopharyngeal carriage of *N. meningitidis* include rifampin, ciprofloxacin, and ceftriaxone. Azithromycin (500 mg) has also been shown to eradicate nasopharyngeal carriage of *N. meningitidis.* Chemoprophylaxis for *H. influenzae* includes rifampin (20 mg/kg once a day for 4 days; maximum of 600 mg/d). Individuals at risk for pneumococcal meningitis (e.g., postsplenectomy) should receive oral penicillin (500 mg every 6 hours for 7 days).

CRITICAL INTERVENTIONS

- If meningitis is suspected, promptly administer antibiotics. Do not wait for the CT scan and the LP.

- Perform a head CT for suspected cerebral mass, focal neurologic findings, papilledema, immunocompromised state, history of CNS disease, new-onset seizure, or altered mental status.
- Provide prophylaxis to individuals who have had close contact with patients diagnosed with meningococcal or *H. influenzae* meningitis.

DISPOSITION

All patients with bacterial meningitis require IV antibiotics and hospital admission. Patients with uncomplicated viral meningitis may be treated with antipyretics and supportive care and may be discharged from the hospital. For patients with suspected viral meningitis who are admitted to hospital, the decision to institute antibiotic coverage in the ED should be made by the emergency medicine physician on the basis of the patient's clinical picture and associated risk factors.

Common Pitfalls

- Failure to make the diagnosis of meningitis in patients with an atypical presentation.
- Failure to suspect meningitis in patients with a negative gram stain and/or a low CSF WBC count.
- Delay in starting antibiotic therapy when there is a reasonable suspicion of meningitis.

CHAPTER 183

Brain Abscess and Other Suppurative CNS Infections

David C. Snow

Central nervous system (CNS) infections are uncommon, yet they can produce serious morbidity and mortality if their diagnosis is delayed. CNS suppurative infections include brain abscess, cranial subdural empyema, cranial epidural abscess, and spinal epidural abscess (SEA). These disease entities must be considered when evaluating patients who present with headache, fever, alteration of consciousness, back pain, or new neurologic deficits. Early identification with the administration of appropriate antibiotics and immediate neurosurgical consultation results in an improved outcome (1).

BRAIN ABSCESS

Brain abscess is a focal infection of the brain parenchyma, accounting for approximately 1 in 10,000 hospital admissions (2). It begins with a localized region of cerebritis, and evolves into a collection of pus surrounded by a capsule (3). Due to improvements in the treatment of ear, sinus, and dental infections the overall incidence of this disease process is decreasing, with only 1,500 to 2,500 cases each year in the United States (4). However, an increase in incidence may be seen as a result of enhanced use of neurosurgical procedures, improved imaging techniques, and increased population of immunocompromised patients (5). It remains the most common

intracranial focal suppurative process and occurs about 2% as often as brain tumors.

There is a 2:1 male-to-female predominance. The age distribution relates to the predisposing condition or risk factor. Brain abscesses from an otic origin usually occur in patients younger than 20 years old or older than 40 years old. Most patients with a paranasal sinus focus are 10 to 30 years of age. Approximately 25% of cases occur in children younger than 15 years old. These cases are most commonly caused by cyanotic congenital heart disease or otic sources. An abscess rarely occurs in children younger than 2 years of age, sometimes occurring secondary to gram-negative bacterial meningitis (2,5).

Brain abscesses can arise from bacterial, mycobacterial, fungal or parasitic infections. They result from either direct spread from a contiguous focus of infection or through hematogenous seeding in the setting of bacteremia (6).

Bacterial brain abscesses are typically the result of contiguous spread from the oropharynx, middle ear, and paranasal sinuses (7). These infections can lead to abscess formation by two mechanisms: by direct extension through infected bone or by retrograde thrombophlebitis from emissary and diploic veins (7). Otitis media (chronic) and mastoiditis classically spread to the temporal lobe (50% to 75% of cases) and the cerebellum (one-third of cases). Approximately 85% to 99% of cerebellar abscesses are from an otic source. Frontal and ethmoidal sinusitis spread to the frontal lobe. Dental sources also tend to affect the frontal lobe (2,5). Penetrating trauma and postneurosurgical procedure abscesses account for between 1% and 12% depending on the case series (8–10).

About 25% of cases arise from hematogenous spread from a cardiac or pulmonary source, including lung abscess, bronchiectasis, cyanotic congenital heart disease (tetralogy of Fallot), and bacterial endocarditis. Most of these sources of hematogenous spread occur from areas of relatively low oxygen tension, leading to a strong predominance of anaerobic organisms. Hematogenously spread abscesses tend to be multiple and lie in the distribution of the middle cerebral artery at the gray-white junction where microcirculatory

flow is the poorest. Other causes include hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease), dental extractions, abdominal or pelvic infections, and following esophageal stricture dilation and endoscopic sclerosis of esophageal varices (2,5). There is no clearly identifiable cause in the remaining 10% to 15% of cases (2).

The blood–brain barrier (BBB) is quite resistant to penetration of these microorganisms from the blood into the brain, which is why this condition is so rare despite the frequency of bacteremia. Improved microbiologic culture techniques have yielded a better understanding of the microbiology of brain abscesses. The most commonly isolated microorganisms are gram-positive cocci and anaerobes (9,10). Aerobic and microaerophilic streptococci (*Streptococcus milleri, Streptococcus viridans*) are the most common gram-positive bacteria isolated, being found in up to 70% of abscesses (5). The most commonly isolated anaerobes are *Bacteroides* sp. (from ear or sinus infection) and anaerobic streptococci (from dental and chronic pulmonary infections). *Staphylococcus aureus* and *Staphylococcus epidermis* are frequently isolated from posttraumatic or postsurgical abscesses (10). Gram-negative bacilli, found in 23% to 33% of cases, are associated with chronic otitis, postoperative infections, and abdominopelvic infection (2,5).

Granulocytopenia, cellular dysfunction, and humoral-mediated immune dysfunction are predisposing factors to the development of CNS infections in immunocompromised patients. Acquired immunodeficiency syndrome (AIDS) and the increasing use of immunosuppressive drug therapy have lead to more atypical, fungal, and protozoal brain abscesses such as *Nocardia* sp., *Listeria* sp., *Cryptococcus* sp., *Mycobacterium* sp., *Aspergillus* sp., and *Candida* sp. Fungi in the order *Mucorales* (*Mucor, Rhizomucor*) can cause abscesses in the setting of chronic sinusitis, most commonly in patients with diabetes mellitus (6). *Toxoplasmosis gondii* is the most common cause of brain abscess in patients with AIDS, and is most commonly seen in those with CD4 counts of less than 100 cells/mm^3 (5,10).

Another important subgroup of patients with a compromised immune system is transplant patients. Brain abscesses occur in approximately 1% of transplant recipients. Fungi, particularly *Aspergillus* sp., are the most frequent etiologic agent (6).

CLINICAL PRESENTATION

The classic triad of fever, headache, and focal neurologic deficit is present in less than half of the patients with a brain abscess (4,5). There are no pathognomonic signs for a brain abscess; therefore, history and a high clinical suspicion are important features for proper diagnosis.

Headache, the earliest presenting symptom, is present in 70% to 80% of patients. The headache is usually insidious, occurring over days to weeks. Abrupt onset of the headache is a poor prognostic indicator. Fever is absent in more than 50% of patients. Alterations in consciousness, ranging from drowsiness to coma, occur in 50% of cases, as do nausea and vomiting. A focal neurologic deficit is seen in 50% to 75% of patients and can include aphasia, hemiparesis, visual field deficits, nystagmus, or ataxia. Cerebellar abscesses are usually associated with ataxia and dizziness. Cranial nerve findings are suggestive of a brainstem abscess. Focal or generalized seizures occur in approximately 30% of cases (1,4,9).

DIFFERENTIAL DIAGNOSIS

Primary or metastatic brain tumor can mimic cerebral abscess on a computed tomography (CT) scan. History and CT appearance easily differentiate other infectious diseases such as viral encephalitis, subdural empyema, epidural abscess, and meningitis.

Immunocompromised patients account for a large proportion of patients presenting to the emergency department (ED) with intracranial mass lesions. Because of the wide variety of pathologic processes involving the CNS of immunocompromised patients, brain biopsy is often needed for definitive diagnosis and treatment. Other considerations in this patient population include *Cryptococcus* sp., *Candida* sp., lymphoma, Kaposi sarcoma, and progressive multifocal leukoencephalopathy.

ED EVALUATION

The history and physical examination should focus on sites of potential infection and the possibility of life-threatening complications. Routine laboratory evaluation is rarely helpful. Leukocytosis may be present, but approximately 50% of patients will have a normal white blood cell count (9). An elevated erythrocyte sedimentation rate is seen in only 40% of cases; however, the C-reactive protein may help to distinguish abscess from tumor. Blood cultures are positive in about 10% of cases but should be obtained even if the patient is afebrile. Chest films may reveal a pulmonic source of infection; sinus or mastoid CT scans may identify infection in these areas.

Lumbar puncture for cerebrospinal fluid (CSF) analysis has a relative contraindication when evaluating for brain abscess. The risk of brainstem herniation is significant and the CSF analysis results typically do not aid in the diagnosis (7,9).

When it comes to neuroimaging, it is important to note that the imaging features of the abscess depend on its stage at the time of the imaging procedure. During the “early cerebritis” stage (first 3 days), a CT scan reveals an irregular area of low density representing focal inflammation and edema. This area does not enhance with contrast and represents the necrotic center of the abscess. In the late cerebritis stage (days 4 to 9), patchy enhancement is present, and the necrotic center develops. As the abscess evolves into the early capsule stage (days 10 to 14), a homogenous central area of low density is seen, and a thick, diffuse, ring-like vascular capsule is present. This enhancement correlates with formation of the collagen capsule. During the late capsule stage (after day 14), the ring becomes thinner as the capsular development progresses, and it is narrower on the ventricular surface of the abscess (3). Features that help to identify the mass as an abscess include gas within the center of the mass, a thinner rim (<5 mm), and ependymal enhancement. Patients given corticosteroids may have diminished enhancement of the abscess ring (5).

Magnetic resonance imaging (MRI) and CT scan are the studies of choice when evaluating a patient for a brain abscess. CT is the

imaging study of choice for the initial evaluation of a patient with a suspected brain abscess, with a reported sensitivity of 95% to 99% (5). MRI has better sensitivity and specificity than contrast CT. MRI is better at detecting mass effect, edema, petechial hemorrhage, smaller lesions, and multifocal involvement (11). Thus, if clinical suspicion is high and a CT scan is negative, an MRI should be performed.

KEY TESTING

- CT (initial imaging) and MRI (higher sensitivity and specificity than CT) are the studies of choice.

ED MANAGEMENT

Initial management of the patient with a suspected brain abscess includes airway control and maintenance of adequate ventilation and circulation. If signs of elevated intracranial pressure and/or impending herniation are present, one must act rapidly to reduce the pressure. These treatments are only temporizing measures and include intubating and hyperventilating the patient, elevating the head of the bed 30 degrees, and instituting pharmacologic therapy with mannitol or hypertonic saline. Corticosteroids remain a controversial topic, but for patients with life-threatening cerebral edema or impending herniation, high-dose corticosteroids may be appropriate (12). Immediate neurosurgical consultation is required, but know that an abscess of less than 2.5 cm in size should do well with medical management alone (10).

Definitive management includes antibiotic therapy and neurosurgical evaluation. The recommended treatment for most abscesses is CT-guided stereotactic or free-hand needle aspiration, with cultures sent to ensure appropriate antibiotic therapy (12). These culture results will not be available during the initial ED evaluation, so antibiotics based on the most likely pathogens should be initiated. Table 183.1 outlines the choices of empiric antibiotics based on the suspected source of the abscess and organisms involved. Pending culture and sensitivity results, one standard regimen
